In the United States, warfarin is still a problem for clinicians because the balanced prothrombin complex concentrates (PCCs) that contain all four factors (II, VII, IX, and X), like KCENTRA for immediate INR reversal, are not readily used by clinicians but are recommended in recent ACCP guidelines.^{38,44} Vitamin K takes days to work, ~4 units of fresh frozen plasma (FFP) is required with transfusion risk issues and volume overload, and FFP never restores the INR to baseline but usually to ~1.4 to 1.6, which is the baseline INR for FFP.⁴⁴

Managing Bleeding with the New Oral Anticoagulants

If patients are acutely bleeding, the new agents as mentioned can be evaluated with specialized tests that should be measured in such patients. For dabigatran, thrombin times (TT) and a diluted thrombin time and ecarin clotting times (used in Europe) are the most sensitive. The aPTT can measure its effects although not as sensitive as a thrombin time.⁴⁵ The aPTT potentially provides a qualitative assessment of anticoagulation. Although there currently is no specific antidote to antagonize the anticoagulant effect of all of the agents, with normal renal function, these agents have a relatively short duration of effect, are direct acting, and drugs should be discontinued when risks of bleeding exceed risks of thrombosis.

With bleeding, patients should be hemodynamically and hemostatically resuscitated, and therapy should be multimodal as outlined previously.⁴² Dabigatran can be dialyzed in patients with renal impairment, but this is not practical in a patient in shock. In instances of life-threatening bleeding, prohemostatic agents such as PCCs can be considered.⁴⁵ For apixaban and rivaroxaban prolongation of most standard hemostatic tests are too variable, and specialized tests evaluating anti-Xa are required.⁴⁶ Our data and others report PCCs completely reverses the anticoagulant effect of rivaroxaban in anticoagulated

patients.^{47,48} Animal data suggest PCCs may actually reverse bleeding and should be considered part of a multimodal approach. However, new specific reversal strategies are in active development.

Of note is that the French Study Group on thrombosis and hemostasis have proposed perioperative management strategies.⁴⁹ They suggest for procedures with low hemorrhagic risk a therapeutic window of 48 hours (last administration 24 hours before surgery, restart 24 hours after). For procedures with medium or high hemorrhagic risk, they suggest stopping therapy 5 days before surgery to ensure complete elimination in all patients. Treatment should be resumed only when the risk of bleeding has been controlled. In patients at high thrombotic risk (e.g., those in atrial fibrillation with a history of stroke), bridging with heparin is proposed. They suggest prohemostatic agents should not be given for prophylactic reversal due to their uncertain benefit-risk.⁴⁹

The major concerns in the ICU are emergency procedures or major bleeding. However, there is increasing information available to facilitate managing patients receiving new oral anticoagulants (NOACs).⁴² Important management of the NOACs is discontinuing its use, but if reversal is required, specific therapeutic approaches should be considered and include the application of PCCs for reversal and/or bleeding. PCCs in the United States are available in four components (KCENTRA) or three components (Profilnine and Bebulin). The 3-component PCCs are deficient in factor VII. We have reported the ability of PCCs to reverse rivaroxaban anticoagulation, and there are increasing reports on their off-label use in bleeding cardiac surgical patients.^{48,50,51}

Despite concerns about NOACs and bleeding, most studies suggest patients fare better on NOACs compared to warfarin.⁵² In one study of 27,419 patients treated up to 3 years, 1034 patients had 1121 major bleeds. The 30-day mortality after the first major bleed was 9.1% in the dabigatran group compared to 13.0% in the warfarin group, and dabigatran-treated patients required a shorter ICU stay compared to warfarin.⁵²

Novel Reversal Strategies for NOACs

Currently, there are no specific reversal strategies available for any of the NOACs although there are three specific reversal agents in development.⁵³ For factor Xa reversal, PRT064445 (andexanet alfa) is a recombinant mimetic of factor Xa that binds to all factor Xa inhibitors and lacks catalytic activity. In current studies involving anticoagulated volunteers, andexanet alfa dose-dependently reversed factor Xa inhibition (clinicaltrials.gov: NCT01758432). For dabigatran reversal, a Fab antibody fragment directed against dabigatran (BI 655075; idarucizumab) is under development in clinical trials, and the FDA granted breakthrough therapy designation to idarucizumab in June 2014 with an ongoing clinical trial: REVERSE-AD (NCT02104947). Two types of patients are being studied: those with serious bleeding and those requiring urgent surgery or intervention. The first data have been reported.⁴³ The third agent is PER977 (aripazine), a cationic small molecule designed to bind all Xa inhibitors including LMWH. Idarucizumab for dabigatran reversal was approved by the FDA in 2015 and is available in most medical centers (<https://www.praxbind.com/>).

■ PLATELET INHIBITORS

In patients with ischemic cardiovascular disease and/or atherosclerotic vascular disease, inhibiting platelet activation is critical in managing these patients.⁵⁴ Platelet inhibitors/antiplatelet agents should also be considered as anticoagulants, but they pose increased risks for bleeding. The antiplatelet agents differ in their modes of action, potency, onsets of action, and indications. Aspirin is an irreversible platelet cyclooxygenase and thromboxane A₂ inhibitor but is also a relatively weak antiplatelet agent,⁵⁵ and resistance can occur.⁵⁶ More potent antiplatelet agents include the P2Y₁₂ receptor and IIb/IIIa receptor antagonists (abciximab, tirofiban, eptifibatide). Clopidogrel, prasugrel, and ticagrelor have become the mainstays of therapy and inhibit platelets by selectively and irreversibly binding to the P2Y₁₂ receptor

to inhibit the adenosine diphosphate–dependent mechanism of glycoprotein IIb/IIIa–receptor expression and platelet activation.^{55,57,58} Clopidogrel is the major agent used with the least knowledge available about how to manage these patients or monitor its effects, and resistance can occur because it is a prodrug and requires metabolism to be transformed to its active metabolite. Dual antiplatelet therapy with aspirin and clopidogrel is standard care following revascularization by PCI with stent insertion. This so-called dual therapy is recommended for up to 4 weeks after intervention for bare-metal stents and for 6–12 months after intervention for drug-eluting stents.⁵⁴ Vincenzi noted a 45% complication rate and a mortality of 20% in patients undergoing noncardiac surgery after coronary artery stenting.⁵⁹ Discontinuation of antiplatelet drugs appeared to be of major influence on outcome. They prospectively evaluated 103 patients receiving stents within 1 year before noncardiac surgery. Antiplatelet drug therapy was not, or only briefly, interrupted. Heparin was administered to all patients. Of 103 patients, 44.7% developed complications after surgery; 4.9% of the patients died. All but two (bleeding only) adverse events were of cardiac nature. Most complications occurred early after surgery. The risk of suffering an event was 2.11-fold greater in patients with recent stents (<35 days before surgery) compared with PCI more than 90 days before surgery.⁵⁹ The clopidogrel package insert suggests if a patient is to undergo elective surgery and an antiplatelet effect is not desired, it should be stopped 5 days before surgery. However, if patients bleed, therapy or monitoring its effects has not been established. Further, the risk compared to the benefit of stopping clopidogrel needs to be weighed against the risk of stent thrombosis, and the need for surgical intervention as well. Prasugrel has an advantage of increased potency and potentially a lower rate of “resistance,”⁶⁰ one of the potential problems for clopidogrel.⁵⁸

ICU/PERIOPERATIVE MANAGEMENT OF ANTITHROMBOTIC THERAPY BASED ON GUIDELINES

Recent guidelines from the American College of Chest Physicians in 2012 have been reported.³⁸ In patients requiring VKA interruption before surgery, they recommend stopping VKAs 5 days before surgery instead of a shorter time before surgery (Grade 1B). In patients with a mechanical heart valve, atrial fibrillation, or VTE at high risk for thromboembolism, they suggest bridging anticoagulation instead of no bridging during VKA interruption (Grade 2C); in patients at low risk, they suggest no bridging instead of bridging (Grade 2C). In patients who require a dental procedure, they suggest continuing VKAs with an oral prohemostatic agent or stopping VKAs 2 to 3 days before the procedure instead of alternative strategies (Grade 2C).

In moderate- to high-risk patients who are receiving acetylsalicylic acid (ASA) and require noncardiac surgery, they suggest continuing ASA around the time of surgery instead of stopping ASA 7 to 10 days before surgery (Grade 2C). In patients with a coronary stent who require surgery, they recommend deferring surgery >6 weeks after bare-metal stent placement and >6 months after drug-eluting stent placement instead of undertaking surgery within these time periods (Grade 1C); in patients requiring surgery within 6 weeks of bare-metal stent placement or within 6 months of drug-eluting stent placement, they suggest continuing antiplatelet therapy perioperatively instead of stopping therapy 7 to 10 days before surgery (Grade 2C).³⁸ In all patients, relative risk versus benefit must be considered when managing patients.

Hematopoietic stem cell transplantation (HSCT) is used to treat an ever-increasing array of disorders, including hematologic and lymphoid cancers, selected solid tumors, and nonneoplastic diseases including autoimmune disorders, amyloidosis, and aplastic anemia. The main indications for autologous transplant include multiple myeloma and lymphomas. Allogeneic transplants are most commonly performed for acute and chronic leukemia, lymphoma, and myelodysplastic syndrome. The most common graft source is peripheral blood; other graft sources include bone marrow and cord blood. A conditioning regimen is employed before transplantation to eradicate malignant cells and, in allogeneic transplantation, to induce immunosuppression that permits engraftment. The conditioning regimen can be myeloablative, reduced-intensity, or nonmyeloablative. Some patients are also given total body irradiation for myeloablation and immunosuppression.

Following HSCT, the immune system recovers along predictable patterns depending on the underlying disorder, stem cell source, and complications such as graft versus host disease (GVHD). Recovery occurs faster in autologous recipients, in those who receive peripheral blood stem cell grafts, and after nonmyeloablative conditioning. The posttransplant period is divided into three phases: preengraftment, early post transplant, and late post transplant. The preengraftment phase (0-30 days) is characterized by neutropenia and breaks in the mucocutaneous barriers. The early postengraftment phase (30 to 100 days) is dominated by impaired cell-mediated immunity. The impact of this cell-mediated defect is determined by the development of GVHD and the corresponding immunosuppressive medications. The late posttransplant phase (>100 days) is characterized by defects in cell-mediated and humoral immunity, as well as function of the reticuloendothelial system in allogeneic transplant recipients.

■ INDICATIONS FOR ICU ADMISSION

Reflecting the multitude of potentially life-threatening complications that can punctuate the posttransplant course, the ICU is a common setting for care of HSCT recipients. Reported rates of admission to the ICU vary widely in the published literature, ranging from 5% to 55% with an overall rate approximating 16%.¹ Pulmonary complications represent the most common reason for ICU admission, accounting for approximately 60% of cases.² Pneumonia and sepsis-induced acute respiratory distress syndrome (ARDS) are common causes of hypoxemic respiratory failure in HSCT recipients. Noninfectious pulmonary complications also can lead to respiratory failure and ICU admission. Finally, airway compromise due to mucositis occasional prompts ICU admission during the preengraftment period.

The second most common reason for ICU admission in this patient population is hemodynamic compromise secondary to sepsis, accounting for approximately 20% of admissions.² Other common reasons are cardiac arrhythmias (8%-17% of cases), intracranial bleeding (2%-5% of cases), seizures (11% of cases), gastrointestinal bleed (5% of cases), and acute renal failure (less than 5% of cases).²

■ COMMON INFECTIOUS COMPLICATIONS REQUIRING ICU CARE

Infectious complications are more common in patients who have undergone allogeneic transplantation since these recipients require the administration of immunosuppressive agents after transplantation to prevent or treat GVHD. In addition, GVHD itself causes an immunodeficient state by involving mucosal surfaces, the reticuloendothelial system, and bone marrow. The use of alternative hematopoietic precursor sources, such as mobilized peripheral blood stem cells, and cytokines, such as hematopoietic cell colony-stimulating factors, have shortened the period of neutropenia and decreased the frequency of infectious pulmonary complications. Additionally, effective prophylactic strategies have evolved that have further reduced the incidence of infections, in particular *Pneumocystis jiroveci* and cytomegalovirus. Nonetheless, pneumonia remains the leading cause of death following HSCT.

Bacterial Pneumonia

Bacterial pneumonia may occur at any time in the posttransplantation period but is particularly prevalent during the preengraftment period of profound neutropenia. Gram-negative pathogens, especially *Pseudomonas aeruginosa* and *Klebsiella pneumoniae*, predominate in the first 100 days, while gram-positive organisms such as *Streptococcus pneumoniae* cause the majority of late infections. *Legionella* species have been reported to be an important cause of nosocomial pneumonia in some centers.

Bacterial pneumonia is commonly heralded by fever, but respiratory symptoms and signs may be absent in the neutropenic host. Presumably because of the paucity of neutrophils, chest x-ray abnormalities may be subtle or absent as well. In one series, the use of high-resolution CT imaging revealed evidence of pneumonia in more than 50% of febrile neutropenic patients with normal chest radiographs.³ Broad-spectrum antibiotics (with anti-*Pseudomonas* activity) should be initiated expeditiously in all suspected cases of bacterial pneumonia and in febrile, neutropenic patients without an identified site of infection.

Aspergillus

Invasive aspergillosis represents one of the most devastating complications of HSCT and remains one of the leading cause of infectious deaths in this group. There is a bimodal distribution of cases, and risk factors for each period are somewhat distinct. Both allogeneic and autologous recipients are at increased risk for invasive aspergillosis during the preengraftment phase, when neutropenia is the prevailing risk factor. Allogeneic HSCT recipients experience a second, postengraftment period of vulnerability coincident with the development of chronic GVHD and the attending physician needs to administer immunosuppressive agents.

Invasive aspergillosis is confined to the lungs in the majority of cases, but sinusitis and central nervous system involvement also occur with some frequency. Cough and dyspnea are the most common presenting symptoms. Pleuritic chest pain and hemoptysis are important albeit nonspecific clues to the presence of invasive aspergillosis, reflecting the tendency of the organism to invade blood vessels and cause pulmonary infarction. Fever may be absent in up to two-thirds of patients.

Initial radiographic findings include single or multiple nodules, cavities, and subsegmental or segmental consolidation. CT imaging is more sensitive in detecting abnormalities and can do so at an earlier stage of infection. A highly characteristic CT finding is the halo sign, a rim of low attenuation representing edema or hemorrhage that surrounds a pulmonary nodule. In one study, the halo sign was present in over 90% of neutropenic patients with invasive pulmonary aspergillosis when CT scans were performed at the onset of fever.⁴

Establishing a definitive diagnosis of invasive pulmonary aspergillosis remains difficult, and up to 30% of cases are unrecognized antemortem.⁵ The recovery of *Aspergillus* species from respiratory tract cultures is highly suggestive of invasive infection in the HSCT population, with a positive predictive value of 82%,⁶ but sensitivity is only 35% to 57%.^{7,8} Transthoracic fine-needle aspiration of accessible focal lesions has a yield of 50% to 67%.^{8,9} An enzyme-linked immunosorbent assay that detects galactomannan, a fungal cell wall component released during invasive disease, has been introduced into clinical practice as a diagnostic tool, albeit with its own limitations. Among HSCT patients with proven or probable cases of invasive aspergillosis included in a meta-analysis, the pooled sensitivity, specificity, and positive and negative predictive values of serum galactomannan testing were 82%, 86%, 65%, and 65%.¹⁰ There are conflicting data on whether galactomannan testing of bronchoalveolar lavage (BAL) performs better than that of serum, with reported sensitivity ranging from 50% to 90% and specificity from 73% to 94%.^{11,12}

Voriconazole is the treatment of choice for invasive aspergillosis, based on demonstration of superior efficacy and less toxicity compared to amphotericin B.¹³ A recent multicenter registry of HSCT recipients documented partial or complete response at 12 weeks in 64% of patients with invasive aspergillosis, the majority of whom were treated with voriconazole alone or in combination with an echinocandin.¹⁴ The mortality rate at this time point was 36%, a dramatic reduction from rates in excess of 80% reported in the 1990s. Surgical resection of localized disease is sometimes used as an adjunct to antifungal therapy in refractory cases.

CMV

The risk of CMV pneumonia is far greater following allogeneic compared to autologous HSCT, a consequence of the need to administer immunosuppressive drugs for GVHD prophylaxis in association with the former procedure. The vast majority of episodes of CMV disease result from reactivation of latent virus in seropositive recipients. Seronegative patients who receive stem cells from a seropositive donor have a lower risk of posttransplantation CMV disease than do seropositive recipients, a situation that contrasts with that seen following solid organ transplantation. In the preprophylaxis era, onset of CMV pneumonia almost invariably occurred between engraftment and day 100. The use of prophylaxis has dramatically reduced the incidence of CMV pneumonia to approximately 5% among allogeneic HSCT recipients but has also shifted the onset of disease to later in the posttransplantation course.

The clinical presentation of CMV pneumonia is not distinctive. Nonproductive cough, fever, and hypoxemia are typical, with rapid progression to respiratory failure in some cases. The chest radiograph most often demonstrates bilateral interstitial opacities, but focal or diffuse consolidation and nodular opacities may also be seen. Ground-glass opacities are commonly demonstrated by high-resolution CT. The diagnosis of CMV pneumonia is most definitively established by demonstration of viral inclusion bodies in specimens obtained by

either transbronchial lung biopsy or BAL, but the yield of both of these techniques is low. In association with compatible clinical and radiographic features, detection of virus in BAL fluid by rapid culture technique or PCR is considered diagnostic in this patient population. However, in cases lacking the classic features, these results must be interpreted with caution since viral shedding into the respiratory tract can occur in the absence of invasive disease. Identification of a high viral load in peripheral blood provides additional supportive evidence in the appropriate setting.

The combination of ganciclovir and high-dose intravenous immunoglobulin or CMV-specific immunoglobulin has become the standard of care for treatment of CMV pneumonia, though the need for the immunoglobulin preparations has recently been challenged.¹⁵ Foscarnet is reserved for patients unable to tolerate ganciclovir and those infected with ganciclovir-resistant strains.

Community Respiratory Viruses

As a group, the community respiratory viral pathogens—respiratory syncytial virus (RSV), influenza A and B, and parainfluenza—account for the majority of non-CMV viral respiratory infections in both autologous and allogeneic HSCT recipients. With the exception of parainfluenza virus, which occurs year-round, the other viruses occur predominantly in the late fall, winter, and early spring. Among patients with RSV infection, the risk of pneumonia approaches 80% for those who are less than 1 month post transplant or still in the preengraftment stage but falls to less than 40% for those beyond this critical period.¹⁶ Once pneumonia develops, mortality from untreated RSV infection approximates 80%. Uncontrolled trials suggest that a combination of aerosolized ribavirin and intravenous immunoglobulin may decrease pneumonia-related mortality when initiated prior to the onset of respiratory failure.^{17,18} Progression to pneumonia occurs considerably less frequently with influenza, though postinfluenza bacterial pneumonias are a concern. The neuraminidase inhibitors zanamivir and oseltamivir are commonly administered, but their efficacy in treatment of influenza pneumonia in HSCT recipients has not been established.

COMMON NONINFECTIOUS COMPLICATIONS REQUIRING ICU CARE

Acute Pulmonary Edema

Acute pulmonary edema is a common but potentially overlooked cause of pulmonary dysfunction during the neutropenic phase following HSCT. Noncardiogenic pulmonary edema has many contributory factors including total body radiation, induction drugs, aspiration, transfusion-related acute lung injury, and sepsis. Patients who develop hydrostatic/cardiogenic pulmonary edema have often received large volumes of fluid for medications, total parenteral nutrition, and multiple blood product transfusions. Cardiac dysfunction resulting from chemotherapeutic agents used during induction can also contribute to volume overload, as can renal impairment.

Engraftment Syndrome and Periengraftment Respiratory Distress Syndrome

Engraftment syndrome is characterized in its full expression by a combination of fever, erythrodermatous rash, diarrhea, diffuse capillary leak, and noncardiogenic pulmonary edema occurring coincident with neutrophil recovery.¹⁹ This syndrome has been described most frequently following autologous HSCT, with a reported incidence of 7% to 53%.^{20,21} A similar presentation following allogeneic transplantation has been described but must be distinguished from acute GVHD. Periengraftment respiratory distress syndrome (PERDS) refers exclusively to the pulmonary component of engraftment syndrome. Recent studies suggest that pulmonary involvement occurs in one-third of patients with engraftment syndrome.²²

The etiology of engraftment syndrome is poorly understood; release of proinflammatory cytokines during engraftment is postulated to play a principal role. The use of granulocyte colony-stimulating factor may increase the incidence and severity of the engraftment syndrome, and discontinuation of this agent is recommended in patients who develop this complication.

Signs and symptoms of PERDS begin within 5 days following neutrophil engraftment. Dyspnea is universally present, accompanied by hypoxemia of varying severity. Frank respiratory failure requiring mechanical ventilator support develops in approximately one-third of patients with PERDS. The majority of patients are febrile; other clinical features of engraftment syndrome may be present, including a maculopapular rash, hypoalbuminemia, ascites, and peripheral edema. Bilateral pulmonary infiltrates are seen on chest x-ray and CT scan but are nonspecific. The diagnosis of PERDS is based on the presence of compatible clinicoradiographic features, onset in the periengraftment period, and the exclusion of infection, volume overload, diffuse alveolar hemorrhage (DAH), and other entities that share similar features. Treatment with high-dose corticosteroids has been associated with rapid clinical improvement, even among patients requiring mechanical ventilation.^{19,23}

Diffuse Alveolar Hemorrhage (DAH)

In the context of HSCT, DAH is considered to be a manifestation of widespread alveolar injury of noninfectious etiology. DAH occurs with a frequency approximating 5% among both autologous and allogeneic HSCT recipients and is encountered in up to 40% of HSCT patients admitted to the ICU.²⁴ DAH is most commonly observed within the first month, often during the periengraftment phase, but later onset is encountered in up to 42% of cases.²⁴ Age > 40 years, total body irradiation, and renal insufficiency have been identified as risk factors.²⁵ Although thrombocytopenia is common, platelet counts are not lower than those found in patients without DAH, and aggressive platelet transfusion does not result in improvement in respiratory status.²⁵

The pathogenesis of DAH in HSCT recipients remains obscure. Postmortem investigations have shown that the majority of patients with DAH have evidence of diffuse alveolar damage.^{25,26} It is likely that DAH, like idiopathic pneumonia syndrome (IPS) and PERDS, is part of a spectrum of acute lung injury induced by conditioning chemotherapy, radiation, and occult infection. The fact that many cases occur at the time of engraftment suggests that neutrophil influx into the lung may accentuate the injury and in some way precipitate hemorrhage.

Patients present with dyspnea, nonproductive cough, fever, and diffuse pulmonary infiltrates, but hemoptysis is notably rare. An otherwise unexplained drop in hemoglobin provides an important clue to the presence of DAH. The majority of patients require ICU admission and mechanical ventilation. Diagnosis centers on the bronchoscopic demonstration of progressively bloodier BAL fluid from at least three lobes or greater than 20% hemosiderin-laden macrophages in the BAL fluid, and the exclusion of underlying infection.

With supportive therapy alone, mortality rates of 80% to 100% have been reported.^{25,27} Onset of DAH within the first 30 days of transplantation and autologous HSCT are associated with the most favorable outcomes, with mortality rates in the range of 30% in association with each of these factors compared to 70% in association with late-onset DAH or allogeneic transplantation.²⁸ Death is usually a result of superimposed multisystem organ failure or sepsis rather than respiratory failure from refractory hemorrhage.²⁴ Retrospective case series and anecdotal reports suggest that high-dose corticosteroids may improve the survival rate but there are no prospective, randomized trials.^{27,29} There are reports of allogeneic HSCT recipients with DAH successfully treated with recombinant factor VIIa.^{30,31}

Idiopathic Pneumonia Syndrome

The term *idiopathic pneumonia syndrome (IPS)* applies to HSCT patients presenting with widespread alveolar injury in the absence of

BOX 141-1 Criteria for Diagnosing Idiopathic Pneumonia Syndrome

- I. Evidence of widespread alveolar injury
 - Multilobar infiltrates on routine chest radiographs or computed tomography
 - Symptoms and signs of pneumonia (cough, dyspnea, tachypnea, rales)
 - Evidence of abnormal pulmonary physiology
 - Increased alveolar to arterial oxygen difference
 - New or increased restrictive pulmonary function test abnormality
- II. Absence of active lower respiratory tract infection based upon
 - Bronchoalveolar lavage cultures, cytology, polymerase chain reaction, and other studies negative for significant bacterial, viral, and fungal pathogens
 - Transbronchial biopsy if condition of the patient permits
- III. Absence of cardiac dysfunction, acute renal failure, or iatrogenic fluid overload as etiology for pulmonary dysfunction

Modified from Panoskaltis-Mortari A, Griesse M, Madtes DK, et al. An official American Thoracic Society research statement: noninfectious lung injury after hematopoietic stem cell transplantation: idiopathic pneumonia syndrome. *Am J Respir Crit Care Med.* 2011;183:1262-79.

an identifiable infectious etiology. More recently, the definition was updated to additionally require exclusion of cardiac dysfunction, renal failure, and iatrogenic volume overload as the etiology for pulmonary dysfunction.³² The updated diagnostic criteria, which continue to rely chiefly on BAL studies to exclude infection, are listed in [Box 141-1](#). Adding to the ambiguity of the definition, some authorities include PERDS and DAH in the spectrum of IPS, while others treat them as distinct entities.

The incidence of IPS in the first 120 days following allogeneic HSCT with myeloablative conditioning is in the range of 3% to 15%.³³ Among allogeneic recipients, the incidence appears to be lower after nonmyeloablative versus conventional high-dose conditioning regimens, lending support to the belief that toxicity from intensive chemotherapy and radiation contributes significantly to pathogenesis. Acute GVHD has been identified as a risk factor for IPS, suggesting that alloimmune mechanisms may also come into play. IPS also occurs following autologous HSCT, but the frequency appears to be lower than that among recipients of allogeneic HSCT. It remains unclear whether the source of stem cells (bone marrow vs. peripheral blood vs. umbilical cord blood) impacts the frequency of this complication.

The median time to onset of IPS has been reported to be 19 days, with the majority of cases occurring within the initial 120 days.³³ Patients with IPS present with dyspnea, fever, nonproductive cough, increasing oxygen requirements, and diffuse radiographic infiltrates. When obtained, lung biopsy specimens reveal two main patterns: diffuse alveolar damage and interstitial pneumonitis. The course is typically rapid, with up to two-thirds of patients progressing within several days to respiratory failure requiring mechanical ventilation.³³ Combined mortality in six of the larger published case series was 74%,³⁴ and the mortality rate among those requiring mechanical ventilation may exceed 95%.³³

Beyond supportive care, there is no proven treatment for IPS. High-dose corticosteroid therapy is commonly administered, but substantiation of benefit is lacking.³³ Based on evidence that anti-tumor necrosis factor therapy mitigates acute lung injury in murine models of IPS,³⁵ etanercept, a soluble tumor necrosis factor- α -binding protein, has been administered to patients with IPS. Two case series, encompassing a total of 37 patients treated with a combination of corticosteroids and etanercept, demonstrated high clinical response rates and improved short-term survival, but pending results of prospective randomized trials, it is premature to endorse this approach as standard of care.^{36,37}

OUTCOMES OF ICU ADMISSION

Historically, the prognosis of HSCT patients admitted to ICU has been poor, but more recent studies have suggested that the prognosis has

improved over the past two decades.³⁸⁻⁴⁰ In a series of HSCT patients requiring ICU level of care at Mayo Clinic between 1982 and 1990, overall hospital mortality was 77%.⁴¹ In a subsequent cohort between 1996 and 2000, the ICU, hospital, and 30-day mortality rates were 33%, 46%, and 52%, respectively.⁴⁰ A retrospective analysis of consecutive patients admitted to a center in the Netherlands documented steady improvement in 100-day posttransplant mortality of patients requiring ICU care, declining from 78% in 2004-2005 to 35% in 2008-2009.⁴²

In particular, HSCT patients requiring mechanical ventilation for respiratory failure have experienced the poorest outcomes, leading some authorities to consider this as a futile intervention in the past.⁴³ In one of the largest studies involving 348 mechanically ventilated HSCT recipients at the Fred Hutchinson Cancer Research Center between 1986 and 1990, survival at 6 months was only 3%.⁴⁴ In another study from the same center, investigators found no survivors among ventilated patients with acute lung injury and either hepatic and renal insufficiency or hemodynamic instability necessitating vasopressors.⁴⁵ Notably, however, more recent studies have reported improved outcomes for HSCT recipients who received mechanical ventilation, with survival rates as high as 26%.^{39,46} These reports are encouraging, and despite the fact that survival rates remain disappointingly low, it can be argued that mechanical ventilation in select groups of HSCT recipients should not be considered futile.

In order to inform the appropriate use of the ICU and mechanical ventilation, a number of studies have attempted to identify factors predictive of outcome. Specific pre-ICU characteristics, including age, sex, primary disease, type of transplant, and conditioning regimen, have not proven to be reliable predictors.^{2,39,46} Admission to the ICU within the engraftment period has been associated with a more favorable prognosis compared to later admission, particularly for recipients requiring mechanical ventilation.⁴⁶ Factors during the ICU course that have been associated with unfavorable outcomes are the need for mechanical ventilation, duration of mechanical ventilation exceeding 4 days, presence of multiorgan failure, hyperbilirubinemia, and use of vasopressors.⁴⁵⁻⁴⁸

Well-known instruments used to prognostically stratify patients at the time of admission to the ICU, such as Acute Physiology and Chronic Health Evaluation (APACHE) II and APACHE III, and the Sequential Organ Failure Assessment have limited prognostic value

in the HSCT patient population. As a result, indices specific to the allogeneic HSCT have been developed. One such index, based on factors present at the time of initiation of mechanical ventilation, classifies patients with a creatinine <2 mg/dL and platelet count >20 × 10⁹/L in a favorable category, with an overall survival at 100 days post mechanical ventilation of 29%, compared to only 5% for those not meeting both of these criteria.⁴⁹ The Hematopoietic Cell Transplantation-Specific Comorbidity Index (HCT-CI), initially developed to predict outcomes after allogeneic HSCT, also appears to be useful as a predictive instrument for in-hospital mortality among patients admitted to the ICU within 100 days of their transplant; in one study, mortality was 46% for those with an HCT-CI score of 0-1 compared to 69% for those with a score ≥4.⁵⁰

These predictive factors and indices allow for some stratification of risk but fall short of defining patients for whom ICU care and mechanical ventilation would be inappropriate. This is best accomplished through daily assessment of the critically ill patient's status and response to therapy, close communication between the ICU and transplant teams, and awareness of the patient's preferences and goals of care.

KEY POINTS

1. Approximately 15% of HSCT recipients will require ICU care at some point in their course.
2. Pulmonary complications, both infectious and noninfectious, represent the leading cause of ICU admission.
3. Bacterial pneumonia is particularly common during the neutropenic preengraftment phase following both allogeneic and autologous HSCT.
4. Because of the requirement for administration of immunosuppressive agents, allogeneic HSCT recipients are particularly predisposed to opportunistic infections, including CMV and invasive aspergillosis.
5. Noninfectious pulmonary complications leading to respiratory failure include PERDS, DAH, and IPS.

Fundamental to the management of a critically ill pregnant woman is a detailed knowledge of the normal physiologic changes that occur during gestation and immediately after delivery. Some of these physiologic adaptations are from the hormonal changes associated with pregnancy, and others are to support the mother and the growing fetus.¹ Clinicians must have a good understanding of the extent of these changes, which occur in all pregnant women, to appropriately diagnose and treat critically ill patients whose additional pathology complicates the distinct metabolic homeostasis and hemodynamics of the normal pregnant state. It is important to recognize that these physiologic changes add a level of complexity to diagnosis and management in the critically ill pregnant woman. The normal baseline physiologic changes of pregnancy often alter the presentation of a disease process or illness that presents during pregnancy, and they can unmask a previously silent disease process of the woman. The normal physiologic maternal adaptations will change the interpretation of clinical and diagnostic examination findings in the pregnant woman. Subsequently, the endpoints of treatment can be significantly different from those for nonpregnant patients.

Some of the physiologic changes associated with pregnancy occur early in the normal course of gestation, whereas others occur during the middle or later stages. To render the most effective care of critically ill pregnant patients, the clinician must be aware of the timing of important physiologic changes. They affect almost all organ systems to varying degrees, depending in part on the gestational age of the fetus. Hemodynamic, metabolic, hormonal, and structural changes all occur during pregnancy and allow for the natural growth and development of the fetus. The healthy pregnant woman adapts remarkably well to these changes, as does the fetus, allowing the two to coexist symbiotically without harm to the other. However, if the pregnant woman is ill, either from a preexisting underlying disease process or from a new pathologic process that occurs during the pregnancy, the normal physiologic adaptive mechanisms of pregnancy are often insufficient to maintain the normal healthy union between mother and fetus. Depending on the severity of the underlying process or new illness, the hemodynamic ramifications to the pregnant woman and her fetus can be devastating and life threatening.

CARDIOVASCULAR CHANGES IN PREGNANCY

Cardiovascular and blood volume changes are among some of the more significant changes that occur in pregnancy (Table 142-1). These changes are primarily adaptive mechanisms, allowing the pregnant woman to accommodate her additional metabolic needs as well as those of the fetus during gestation and immediately after delivery. Cardiac output is significantly increased during pregnancy by as much as 50% compared with nonpregnant values. Cardiac output is increased by 15% in twin pregnancies as well as in multiple gestations.^{2,3} The dramatic rise in cardiac output is seen as early as the first 6 to 8 weeks of pregnancy. After the 10th week, cardiac output is increased by 1 to 1.5 L/min, increases by 75% by the end of the third trimester, and reaches a maximum value by approximately the 20th to 24th week of gestation. The early increase in cardiac output is primarily due to a significant increase in stroke volume. However, stroke volume decreases as the pregnancy advances because of aortocaval compression by the

uterus and the pressure of the fetal presenting part on the common iliac vein. Caval compression occurs because the large, gravid uterus rests on the vena cava, decreasing venous return to the heart and therefore effectively decreasing ventricular preload. In the latter half of pregnancy, a progressive increase in the maternal heart rate by 15 to 20 beats/min is primarily responsible for maintaining the elevated cardiac output. The additional increase in cardiac output before labor and delivery is caused by a further increase in heart rate. Resting cardiac output either is maintained or decreases slightly as term approaches.⁴

Influence of Body Position

Venous return is further compromised with changes in body position, particularly if the pregnant patient is supine. As a result, cardiac output can be diminished by as much as 25% to 30%. The effects of changes in body position are most obvious in the latter half of pregnancy when the fetal size and gravid uterus can effectively tamponade the vena cava, the abdominal aorta, and the iliac arteries. This phenomenon is exaggerated in women with poorly developed venous collaterals. With compression of the vena cava in the supine position, these women exhibit signs of severe hypoperfusion (hypotension and bradycardia), a phenomenon described as the *supine hypotensive syndrome of pregnancy*. Symptoms quickly resolve after the patient is repositioned to the left lateral recumbent position.⁵ Cardiac output can decrease by 30% to 40% in patients with this syndrome. This vasovagal phenomenon underscores the influence of maternal body position on the hemodynamic alterations occurring in pregnancy.

Hemodynamic changes associated with decreases in preload and cardiac output are less pronounced when the gravid uterus is minimally compressing the vena cava, which is optimally achieved by maintaining the pregnant woman, at greater than 20 weeks' gestation, in the left lateral position when recumbent. Alternatives to this position, less optimal than the left lateral position but preferable to the supine position, are a left lateral tilt to 15 degrees or manual displacement of the gravid uterus. The latter maneuver of left uterine displacement can be performed by manually moving the uterus away from the midline to the left side when the patient is supine. This maneuver is particularly useful when performing cardiac compressions in a pregnant patient. In the supine position, the gravid uterus, which accounts for as much as 10% of the cardiac output, hinders successful resuscitation because of its adverse effects on intrathoracic pressure and venous return. Although hemodynamics are best in the left lateral position, it is difficult to achieve optimal chest compressions with the patient in the left lateral decubitus position. Acceptable alternatives are to perform cardiac compressions with the patient supine but with concurrent manual displacement of the uterus to the other side; it is also satisfactory to place a firm wedge under the right hip of the patient.^{6,7}

Oxygen Consumption and Ventricular Performance

As cardiac output progressively increases, maternal oxygen consumption also increases. However, the increase in cardiac output is seen earlier than the rise in maternal oxygen consumption. Accordingly, the arteriovenous oxygen difference actually narrows early in pregnancy.

TABLE 142-1 Normal Hemodynamic Changes During Pregnancy

| PHYSIOLOGIC PARAMETER | TERM PREGNANCY | LABOR AND DELIVERY | POSTPARTUM |
|------------------------------|---|---|------------------------------------|
| Cardiac output | Increases 30%-50% | Increases 50% | Increases 60%-80% within 15-20 min |
| Blood volume | Increases 30%-50% | Additional 300-500 mL with each contraction | Decreases to baseline |
| Heart rate | Increases by 15-20 beats/min | Increase depends on stress and pain relief | Decreases to baseline |
| Blood pressure | Decreases by 5-10 mm Hg in midpregnancy | Increase depends on stress and pain relief | Decreases to baseline |
| Systemic vascular resistance | Decreases | Increases | Decreases to baseline |
| Oxygen consumption | Increases by 20% | Increases with stress of labor and delivery | Decreases to baseline |
| Red blood cell mass | Increases by 15-20% | — | — |

The arteriovenous oxygen difference widens at the end of gestation. By term, there is a 20% increase in maternal oxygen consumption, mostly as a result of the increase in metabolic needs of the fetus. The increase in oxygen consumption is also a result of maternal increased work of ventilation during pregnancy, maternal increase in myocardial oxygen demand, and maternal increase in renal oxygen consumption. Oxygen extraction also gradually increases throughout gestation. The increase in cardiac output is probably the result of a combination of factors including increased uterine blood flow, increased maternal circulating blood volume (and hence ventricular preload), and possibly estrogen- and prolactin-induced augmentation of myocardial contractility. Ventricular dynamics are improved during pregnancy as a direct result of the action of steroid hormones on the pregnant myocardium. In animal models, estrogens have been shown to increase cardiac output and decrease peripheral vascular resistance.⁸ Echocardiographic studies performed in healthy pregnant women have demonstrated a decrease in the prejection period of left ventricular systole but an increase in the left ventricular end-diastolic dimension.⁹⁻¹¹ It may be that a combination of improved myocardial contractility and increased ventricular diastolic area may be responsible for increases in cardiac output during normal pregnancy.¹²

Hemodynamic Changes During Labor and Delivery

Although cardiac output remains relatively constant in the latter half of pregnancy, there is a significant increase during active labor and immediately after delivery. With each uterine contraction, cardiac output dramatically increases as an additional 300 to 500 mL of maternal blood volume from the uterus is returned to the heart. Cardiac output can rise to 50% greater than normal when the pregnant woman is pushing in the second stage of labor. The amount of blood returned to the heart is accentuated in the supine position. When the pregnant patient is supine, uterine contractions can cause a 25% increase in

cardiac output, a 15% decrease in maternal heart rate, and a 30% to 35% increase in stroke volume. In the lateral recumbent position, the hemodynamic changes associated with uterine contractions are less pronounced; cardiac output and stroke volume may rise by only 6% to 7%, and there may be only a small change in maternal heart rate. Cardiac output may be preferentially diverted to the heart if there is partial obstruction of the abdominal aorta by the uterus during contraction.

The hemodynamic changes seen during labor and delivery are influenced by anesthetic and analgesic techniques. The increase in cardiac output is less if caudal anesthesia is used.^{13,14} Within the immediate 20 to 30 minutes after delivery of the fetus and placenta, there is an even greater increase in cardiac output, because blood is no longer diverted to the uteroplacental vascular bed. Approximately 500 mL is redirected to the maternal circulation in the so-called autotransfusion effect of pregnancy. This effect can increase cardiac output by 60% to 80% after aortocaval compression is removed and blood volume is increased. Many of the physiologic changes of pregnancy resolve and revert to normal within several days after delivery. Cardiac output returns to normal within 2 weeks to 3 months after delivery as sodium and water balances normalize.

Blood Volume Changes

The changes in maternal blood volume during pregnancy are significant. Plasma volume increases by 30% to 50% by the end of gestation. This value is increased in the multigravida patient compared with primigravidas, but the exact mechanism responsible for this effect is unclear. The increase in blood volume can be as high as 70% with twin pregnancies. An increase of 10% to 15% in blood volume is seen as early as the sixth week of gestation. Blood volume is maximal at 30 to 34 weeks, after which the value plateaus until term.¹⁵ Others have suggested that blood volume continues to increase until term.¹⁶ Ventricular filling pressures do not increase despite the large increases in plasma volume.¹⁷ This is most likely the result of vasodilatation with concurrent decreases in systemic and pulmonary vascular resistance as well as a normal heart adapting to chronic volume overload.

The increase in blood volume is a striking adaptive mechanism that permits additional blood flow to the uterus and other maternal organs, in particular the kidneys. Uterine blood flow increases to 100 mL/min by the end of the first trimester and reaches 1200 mL/min at term. Both sodium and water retention contribute to the increase in plasma volume. Total body water increases by approximately 6.5 to 8 L. Most of this increase is seen in the extracellular space and is preferentially distributed in the lower extremities. The total increase in body water includes approximately 3.5 L of amniotic fluid, placental fluid, and water in the fetus. The relative hypervolemia leads to a mild reduction in the serum sodium concentration (135-138 mEq/L) and in serum osmolality (approximately 280 mOsm/L). The maternal blood volume increases by 1 to 2 L. Red blood cell (RBC) mass accounts for only 300 to 400 mL of the increase in total blood volume.

Plasma renin and aldosterone levels are elevated during pregnancy despite expansion of the maternal blood volume. Activation of the renin-angiotensin-aldosterone system may result from the concomitant decrease in peripheral vascular resistance and the increase in vascular capacitance seen as early as the first 6 weeks of pregnancy.³ Both estrogens and progesterone increase aldosterone levels, increasing sodium and water retention.¹⁸ At 12 weeks of gestation, atrial natriuretic peptide levels also increase, most likely in response to the increase in plasma volume.

The increase in blood volume is an adaptive mechanism that provides some level of protection for the inevitable blood loss that accompanies delivery of the fetus and placenta.^{19,20} Average blood loss during vaginal delivery is 500 mL; average blood loss during cesarean delivery is approximately 1000 mL. Although providing some degree of protection from peripartum blood loss, the increased plasma volume associated with pregnancy also can lull the clinician into a false sense of security. A pregnant woman can lose up to 35% of her blood volume

before the usual signs of hypovolemia and acute hemorrhage are obvious. Although the pregnant woman may appear to have stable vital signs up to this point, the fetus may be severely compromised and deprived of adequate maternal blood flow. Tachycardia, hypotension, and other signs of hemodynamic instability are late manifestations of a significant deficit in maternal blood volume.

Physiologic Anemia of Pregnancy

Accompanying the increase in blood volume is an increase in RBC mass stimulated by increased circulating levels of erythropoietin. The RBC mass increases during the second trimester and continues to increase progressively throughout the pregnancy. However, the increase of 15% to 20% in RBC mass is disproportionate to the 30% to 50% increase in blood volume. As a result, the hematocrit decreases, resulting in the “physiologic hemodilutional anemia” of pregnancy. Hemodilution is most notable during the 30th to 34th gestational weeks. The hemoglobin concentration can decrease by as much as 9%. In the second trimester, the hemoglobin level can decrease to 11 to 12 g/100 mL, compared with the normal nonpregnant value of 13 to 14 g/100 mL. The decrease in blood viscosity associated with the anemia of pregnancy allows for a decrease in resistance to blood flow that improves placental perfusion. The hematocrit decreases until the end of the second trimester but increases later in the pregnancy, when the increase in RBC mass is proportionate to the increase in plasma volume. The hematocrit stabilizes at that point or even increases slightly as term approaches.

The degree of change in RBC mass during pregnancy depends in part on whether iron is supplemented. With the increase in RBC mass, there is a need for additional iron to prevent the development of iron-deficiency anemia. Maternal requirements for iron can increase to 5 to 6 mg/d. The fetus uses iron from maternal stores to prevent fetal anemia, but the presence of significant maternal iron-deficiency anemia has been shown to result in a higher incidence of fetal complications, including preterm labor and late spontaneous abortions.²¹

Renal Blood Flow During Pregnancy

Under the influence of circulating hormones, there is a preferential redistribution of blood flow to the uterus, breast, and kidneys during pregnancy. Each kidney increases in length and weight, and the renal pelvis and ureters dilate, leading to urinary stasis that predisposes pregnant women to frequent urinary tract infections.²² The glomerular filtration rate (GFR) increases by 50%, and renal blood flow increases by 60% to 80% above prepregnancy levels.²³ Changes in GFR and renal blood flow occur by the sixth week of gestation. The increase in renal blood flow plateaus early in pregnancy and remains unchanged or decreases slightly as term is approached. Urine flow and sodium excretion are increased and are influenced by position, especially in late pregnancy. Flow rates and the sodium excretion rate are significantly higher in the lateral recumbent position compared with the supine position. Concentrations of serum creatinine and blood urea nitrogen are reduced proportionately to the increase in GFR. Glycosuria may also occur during pregnancy as a result of the increase in GFR and impaired tubular reabsorption of glucose.

Changes in Blood Pressure and Vascular System

Systolic and diastolic blood pressures usually decrease by 5 to 10 mm Hg below the patient's baseline blood pressures in the second trimester and may normalize to nonpregnant values by term.²⁴ Arterial blood pressure decreases as early as the sixth week of pregnancy; the lowest diastolic pressures are recorded during the second trimester. By the eighth week of gestation, diastolic blood pressure decreases by approximately 10%. Diastolic pressure reaches a nadir at 16 to 24 weeks and is typically 5 to 10 mm Hg less than normal. After the 16th to 24th gestational weeks, blood pressure progressively increases and is back

to baseline by term. With the increase in venous return associated with uterine contractions and the additional factors of pain, anxiety, and stress during labor and delivery, an increase in blood pressure usually occurs during this time. Although earlier studies showed that blood pressure decreases during pregnancy, recent studies have demonstrated progressive increases in blood pressure during pregnancy, particularly in obese and overweight women.^{25,26} The decrease in blood pressure during pregnancy is associated with a significant decrease in peripheral vascular resistance. Decreased systemic vascular resistance begins as early as the 5th week of gestation and plateaus between the 20th and 32nd weeks, after which it slowly increases to prepregnancy values by term.²⁷ The decrease in arteriolar tone is influenced by several factors, including hormonal changes that induce vasodilatation and lack of responsiveness to the pressor effect of angiotensin II.²⁸ There is evidence for blood vessel remodeling in pregnancy, leading to increased venous compliance.^{29,30} During pregnancy, circulating levels of numerous endogenous procoagulant and anticoagulant proteins change, leading to a hypercoagulable state. As a consequence, the risk of venous thrombosis increases during pregnancy. The reported incidence is 0.7 cases per 1000 women, and this rate increases threefold to fourfold in the postpartum period.³¹

The treatment of choice for severe hypotension resulting from acute hemorrhage, sepsis, or other critical illness during pregnancy is aggressive fluid resuscitation. When hypotension is refractory and unresponsive to fluids, vasopressors should be used to prevent detrimental consequences of the hypotension to both the mother and fetus as a result of inadequate uterine blood flow. Most vasopressors increase maternal blood pressure at the expense of fetal blood flow, inducing vasoconstriction of the uterine vessels. There are few human studies of these agents in pregnant women. However, animal studies have indicated that epinephrine and dopamine increase uterine blood flow to the uteroplacental circulation while at the same time increasing maternal blood pressure.³²

Structural Remodeling of the Heart

The heart is dramatically remodeled during the first few weeks of pregnancy. There is enlargement of all four chambers. The valvular annular diameters increase, as do the thickness and volume of the left ventricular wall. End-diastolic volume increases, although end-diastolic pressure remains unchanged.^{11,30} Chamber enlargement, particularly of the left atrium, may be a predisposing factor for supraventricular and atrial arrhythmias. Nonspecific ST-T wave changes may also be found in asymptomatic pregnant woman.

As the uterus enlarges and the diaphragm elevates, the heart is rotated upward and to the left. The apical impulse on physical examination is heard best over the fourth intercostal space, lateral to the midclavicular line. Left axis deviation is seen on the electrocardiogram as a result of the rotation of the heart. Because of the displacement of the heart, pregnant women may appear to have cardiomegaly on the chest radiograph. In addition, lung markings may be more prominent, suggesting vascular congestion. These changes can be similar to those seen in patients with heart disease. Even in women with no underlying cardiac pathology, the normal physiologic changes of pregnancy can result in signs and symptoms that are difficult to differentiate from those associated with cardiac disease. Symptoms such as fatigue, decreased exercise tolerance, peripheral edema, palpitations, chest pain, dyspnea, and orthopnea are common complaints as pregnancy advances.

New murmurs often appear during pregnancy. Systolic flow murmurs and a third heart sound are common but are soft. Mild pulmonic and tricuspid regurgitation occurs in more than 90% of healthy pregnant women.^{33,34} One-third of pregnant women have evidence of clinically insignificant mitral regurgitation. Diastolic, pansystolic, and late systolic murmurs are rare in normal pregnancy and may indicate underlying heart disease. As a result of the mild 4-chamber dilatation, clinically insignificant mitral, tricuspid, and mitral regurgitation is seen. Bruits originating from the internal mammary artery

and venous hums with diastolic components are common during pregnancy. These findings can initially confuse the diagnosis of a more serious underlying cardiac illness.

Cardiac Disease and Pregnancy

In women with significant cardiac pathology, the hemodynamic aberrations associated with pregnancy can be life threatening. The incidence of significant cardiac disease in pregnancy is less than 2% but is increasing.^{35,36} Advances in medical therapy and in cardiac surgery including transplantation have allowed female cardiac patients to survive to childbearing age and to have successful term pregnancies.³⁷ For women with severe cardiac problems such as pulmonary hypertension, Eisenmenger's syndrome, severe mitral stenosis, or Marfan's syndrome (in which the risk of aortic dissection is high during pregnancy), the physiologic changes of pregnancy can increase both maternal and fetal morbidity and mortality by transiently or permanently worsening the underlying heart disease.³⁸ Increases in blood volume, stroke volume, cardiac output, and heart rate and the decrease in systemic vascular resistance are poorly tolerated by pregnant women with severe underlying cardiac disease. Maternal mortality is less than 1% for patients with less severe cardiac problems, but it increases to 50% if pregnancy is associated with the presence of underlying primary pulmonary hypertension or cyanotic disorders such as Eisenmenger's syndrome.^{39,40}

Approximately 90% of pregnant women with cardiac disease are rated as New York Heart Association (NYHA) functional class I or class II. These patients tolerate the hemodynamic changes of pregnancy and can be managed well with medical therapy, although the incidence of heart failure and arrhythmias tends to be higher in this group of patients.⁴¹ The 10% of pregnant patients with NYHA functional class III or IV heart disease account for 85% of cardiac deaths.⁴² Fetal morbidity and mortality are increased in these patients, and there is a higher incidence of prematurity, miscarriage, and intrauterine growth retardation.⁴³ Cardiac telemetry, fetal monitoring, and hemodynamic monitoring are usually necessary for these high-risk patients during labor and delivery and, because of the large changes in intravascular volume after delivery, during the first few postpartum days.

ENDOCRINE AND METABOLIC CHANGES IN PREGNANCY

There are numerous endocrine and metabolic alterations during pregnancy, many of which are directly attributable to hormonal signals originating from the fetoplacental unit. Maternal adaptations to hormonal changes that occur during pregnancy directly influence the growth and development of the fetus and placenta. In pregnancy, there is also a change in the normal hormonal feedback mechanisms that control the synthesis and release of hormones. As with cardiac disease, the presentation of endocrine and metabolic disorders may be difficult to differentiate from the normal hypermetabolic state of pregnancy.

Hypothalamic and Pituitary Alterations

As in the nonpregnant state, the hypothalamic-pituitary axis is responsible for regulating many aspects of metabolism. Circulating levels of most of the releasing hormones of the hypothalamus increase during pregnancy because of increased production by the placenta rather than increased production and release by the hypothalamus. The target organ of the hypothalamus, the pituitary gland, undergoes remarkable structural and metabolic changes in pregnancy. Its size increases almost threefold secondary to estrogen stimulation. Gonadotropin and growth hormone production decrease during pregnancy. However, synthesis of ACTH, prolactin, and thyroid-stimulating hormone (TSH) increases.

Free and bound cortisol levels are increased in pregnancy, even though circulating ACTH concentrations are elevated. These changes suggest that the normal negative feedback loop between ACTH and

cortisol concentrations is altered in the pregnant state.⁴⁴ Free plasma cortisol concentrations may be two to three times higher than normal at term. Diurnal variation of cortisol is blunted but maintained throughout pregnancy. The clinical signs of weakness, peripheral edema, glucose intolerance, and weight gain associated with Cushing's disease are sometimes difficult to differentiate from the clinical features of normal gestation. The symptoms of Cushing's disease are exacerbated by pregnancy but often resolve after delivery. Improved outcomes are seen with surgical therapy in partum, if pituitary or adrenal tumors are discovered during the course of the pregnancy.^{38,45} In normal pregnancy, cortisol release may not be suppressed with a low intravenous dose (1 mg) of dexamethasone. An 8-mg dose of dexamethasone is usually needed to suppress cortisol secretion if a tumor is present. In patients with occult adrenal insufficiency, a life-threatening adrenal crisis may be precipitated by the stress of labor and delivery. During pregnancy, the signs and symptoms may be vague and nonspecific, but with the stress of labor, these symptoms are exaggerated. The clinical diagnosis is made in conjunction with laboratory evidence of a low cortisol level or even a low-normal level and no increase in the plasma cortisol concentration with an ACTH stimulation test. Immediate treatment with stress doses of hydrocortisone is indicated in these patients.

In preparation for lactation, circulating prolactin levels progressively increase to about 10 times normal during the course of pregnancy, secondary to stimulation of the anterior pituitary by placental estrogens and progesterone. The dramatic increase in plasma prolactin concentration may lead to an increase in size of preexisting pituitary adenomas larger than 1 cm.⁴⁶ Symptoms resulting from an increase in prolactin secretion usually subside within 6 weeks after delivery if the patient is not breastfeeding.

The thyroid gland increases the production of thyroid hormones during pregnancy. TSH secretion is transiently decreased in the first trimester, but circulating TSH concentrations are usually increased by term. Circulating levels of thyroxine (T_4) and triiodothyronine (T_3) increase as a result of a twofold estrogen-stimulated increase in the synthesis of thyroxine-binding globulin. Levels of free (dialyzable) T_4 and free T_3 are unchanged. In 15% of women, the thyroid gland increases in size and volume. Pregnant women who obtain sufficient dietary iodine (more than 200 μ g daily) have no untoward complications from the changes in thyroid function.^{47,48} Patients with preexisting hypothyroidism should increase their levothyroxine daily dose by 30% early in pregnancy.⁴⁹

Posterior pituitary hormones are altered in pregnancy. Circulating oxytocin levels increase, but the vasopressin concentration remains essentially unchanged. Plasma osmolality decreases by 5 to 10 mOsm/kg, suggesting that the threshold for secretion of vasopressin decreases during gestation. Although vasopressin levels remain unchanged, some women develop transient diabetes insipidus during pregnancy.⁵⁰

Changes in Glucose Metabolism

Early in pregnancy, increased levels of estrogens and progesterone influence glucose metabolism primarily by inducing pancreatic β -cell hyperplasia and increased insulin secretion. Placental hormones control glucose metabolism later in the pregnancy in response to the increased nutritional and metabolic demands of the fetus. Circulating glucose and insulin levels fluctuate widely depending on the nutritional state of the mother. Morning fasting levels of glucose can decrease to less than 55 mg/dL. Fasting blood glucose levels decrease by 10% to 20% because of increased peripheral glucose utilization, decreased hepatic glucose production, and increased consumption of glucose by the fetus.

Pregnant women with diabetes mellitus experience more hypoglycemic episodes in the first trimester, because hepatic gluconeogenesis is decreased during this period. Insulin secretion increases during pregnancy. There is a relative state of insulin resistance, as evidenced by postprandial maternal hyperglycemia.⁵¹ Normally, women adapt to the state of relative insulin resistance during pregnancy. However,

those women with marginal pancreatic reserve or preexisting insulin resistance due to obesity may not produce sufficient insulin, leading to the development of gestational diabetes mellitus. Pregnant women with preexisting diabetes mellitus require as much as 30% more insulin than before pregnancy. There is a close correlation between maternal blood glucose levels and glucose uptake and utilization by the fetus, because glucose crosses the placental barrier. Poor maternal glucose control worsens fetal morbidity. For patients with preexisting insulin-dependent diabetes mellitus, fetal and neonatal mortality rates have

decreased significantly, from 65% to between 2% and 5%, as a result of implementing strict metabolic glucose control with insulin.⁵²

Lipid metabolism is accelerated in pregnancy, and the circulating concentrations of triglycerides and cholesterol increase. Increased production of triglycerides allows for maternal consumption while sparing glucose for use by the fetus.⁵³ Lipolysis is stimulated in adipose tissue, and there is a release of glycerol and fatty acids that decreases maternal glucose utilization, additionally sparing glucose for the fetus.

KEY POINTS

1. Normal pregnancy is associated with numerous physiologic changes that affect almost all maternal organ systems.
2. Hemodynamic, metabolic, hormonal, and structural changes that occur during pregnancy are adaptive mechanisms for maintaining a healthy homeostasis between the mother and the fetus.
3. Maternal hemodynamic alterations and poor fetal outcome can occur if the physiologic adaptive mechanisms are insufficient to maintain the normal homeostasis between the mother and the fetus.
4. The physiologic changes occur at different stages throughout the pregnancy.
5. The normal physiologic changes of pregnancy may alter the presentation of a maternal disease process, confound the diagnosis, or alter the endpoints of treatment.
6. Cardiac output is increased significantly, up to 50% above prepartum values, by the 24th week of gestation. The value then plateaus until term. During labor and delivery, cardiac output is further increased with uterine contractions and the "auto-transfusion" effect of increased preload after delivery of the fetus and placenta.
7. The increase in cardiac output early in pregnancy is primarily caused by an increase in blood volume. Later in pregnancy, an increase in the heart rate by 15 to 20 beats/min is mainly responsible for the increase in cardiac output. Improved myocardial contractility may account in part for an improvement in cardiac output in pregnancy.
8. Maternal body position directly affects cardiac output and stroke volume. In the supine position, the gravid uterus causes aortocaval compression and decreased preload. An extreme manifestation of this effect is the "supine hypotensive syndrome" of pregnancy.
9. After the 20th week of gestation, pregnant women should not be placed supine but rather in the left lateral recumbent position, which maximizes maternal hemodynamics. During cardiac resuscitation, the pregnant patient should be placed in this position, or manually displace the uterus to the left.
10. Left ventricular end-diastolic volume is increased during pregnancy, but filling pressures are relatively unchanged; this may reflect the decrease in afterload caused by a decrease in systemic and pulmonary vascular resistance.
11. Blood volume increases by 30% to 50% by the end of gestation. However, red blood cell mass increases by only 15% to 20%, creating the "physiologic anemia" of pregnancy.
12. A pregnant woman can lose up to 35% of her blood volume before tachycardia and hypotension occur as a result of acute hemorrhage or severe hypovolemia.
13. Blood flow is increased to many organs during pregnancy, especially to the breasts, uterus, and kidneys. Renal blood flow increases by 25% to 50%, and the glomerular filtration rate increases by up to 50%, with a decrease in the plasma creatinine and blood urea nitrogen concentrations.
14. A decrease in the diastolic blood pressure by 10% is seen in the second trimester, secondary to the decrease in systemic vascular resistance. By the end of pregnancy, blood pressure levels should increase to prepartum values.
15. Blood vessel remodeling and changes in the coagulation system during pregnancy, including an increase in most clotting factors, makes the pregnant woman hypercoagulable and more susceptible to venous thromboembolism throughout pregnancy and in the postpartum period.
16. Remodeling of the heart causes enlargement of all four chambers. The pregnant woman may be more susceptible to supra-ventricular and atrial arrhythmias because of left atrial enlargement.
17. Systolic ejection murmurs and a third heart sound can commonly be heard during pregnancy. Diastolic, pansystolic, and late systolic murmurs should prompt the clinician to look for an underlying cardiac problem.
18. Pregnant patients with mild to moderate cardiac disease usually tolerate the hemodynamic changes of pregnancy. Those patients with pulmonary hypertension and right-to-left shunts have mortality rates as high as 50%.
19. There are numerous endocrine and metabolic alterations during pregnancy that primarily affect the hypothalamus, pituitary, and adrenal glands. As with cardiac disease, the presentation of a patient with endocrine and metabolic disorders may be difficult to differentiate from the normal hypermetabolic state of pregnancy.
20. Both corticotropin (ACTH) and cortisol levels are elevated in pregnancy. Cushing's syndrome can be exacerbated by pregnancy. Acute adrenal crisis may be precipitated by the stress of labor and delivery. The treatment is immediate glucocorticoid administration.
21. In preparation for lactation, prolactin levels are increased 10-fold throughout the pregnancy as a result of estrogen and progesterone stimulation. This increase in prolactin may

KEY POINTS—cont'd

- increase the size of pituitary adenomas and precipitate symptoms during the pregnancy.
- 22. Thyroid hormones are increased during pregnancy as a result of increased synthesis of thyroxine-binding globulin. Free levels are unchanged. Despite the complex thyroidal changes that occur during pregnancy, pregnant women have no untoward complications if their daily iodine intake is sufficient.
- 23. Transient diabetes insipidus can develop during pregnancy, secondary to a state of vasopressin resistance.
- 24. Large fluctuations in glucose and insulin levels are seen in pregnancy, depending on the nutritional state of the mother. Fasting glucose levels can decrease by 10% to 20%.
- 25. During pregnancy, there is increased insulin secretion, with a relative state of insulin resistance.
- 26. Obese women with insulin resistance and women with marginal pancreatic reserve can develop gestational diabetes mellitus.
- 27. Fetal and neonatal mortality rates are low if strict metabolic glucose control with insulin therapy is maintained.
- 28. Maternal lipid metabolism is increased during pregnancy, allowing for increased glucose utilization by the fetus.

ANNOTATED REFERENCES

- Recommendations and guidelines for CPR and ACLS drug administration in pregnancy are presented by the AHA. Evidence extrapolated from periarrest resuscitation scenarios indicated that ultrasound assessment undertaken by trained rescuers may help to identify intraabdominal hemorrhage as a cause of cardiac arrest in pregnancy in the hospital setting. Clinicians are advised to identify common and reversible causes of cardiac arrest in pregnancy during the resuscitation attempts. The use of abdominal ultrasound by a skilled operator should be considered in detecting pregnancy and possible causes of cardiac arrest in pregnancy, but this should not delay other treatments.

- This landmark paper presents central hemodynamic data obtained with the use of a pulmonary artery catheter during pregnancy and after delivery. Ten primigravida patients in late pregnancy (between the 36th and 38th weeks of gestation) underwent pulmonary artery catheter and arterial catheter placement. These same patients were restudied with a pulmonary artery catheter at 11 to 13 weeks after delivery. All measurements were performed with the patient in the left lateral recumbent position. The authors found significant decreases in systemic vascular resistance, pulmonary vascular resistance, colloid oncotic pressure, and colloid oncotic pressure-pulmonary capillary wedge pressure gradient in the third-trimester measurements ($P < 0.05$). A significant rise in cardiac output and heart rate was seen in all patients before delivery ($P < 0.05$). No significant changes in pulmonary capillary wedge pressure, central venous pressure, left ventricular stroke work index, or mean arterial pressure were found. Although blood volume and preload are elevated in pregnancy and end-diastolic volume increases, there were no substantial increases in the filling pressures of the heart as measured by the pulmonary artery catheter, suggesting a decrease in afterload with the decrease in the systemic and pulmonary vascular resistance.

- Recommendation 4: There is insufficient evidence to make specific recommendations for types of anticoagulation management of VTE in pregnant women. During pregnancy, women have a fivefold increased risk for VTE compared with nonpregnant women. Clinicians should avoid vitamin K antagonists in pregnant women, because these drugs cross the placenta and are associated with embryopathy between 6 and 12 weeks' gestation, as well as fetal bleeding (including intracranial hemorrhage) at delivery. Neither LMWH nor unfractionated heparin crosses the placenta, and neither is associated with embryopathy or fetal bleeding.

- This article is an excellent review of cardiac disease in pregnancy, focusing on the different causes of cardiac disease and their management in pregnancy. Cardiac disease is the most common cause of mortality in pregnancy and may present with cardiovascular decompensation during pregnancy, at the time of delivery, or immediately postpartum. The goals of therapy are early risk assessment, optimization, regular monitoring for deterioration, planning of delivery, and surveillance for deterioration in the immediate postpartum period. Vaginal delivery with low-dose regional analgesia and careful fluid management is the preferred method of delivery, and cesarean section deliveries should be reserved for obstetric indications.
- Van De Velde M, De Buck F. Anesthesia for non-obstetric surgery in the pregnant patient. *Minerva Anesthesiol* 2007;73:235-240.
- Surgery during pregnancy is relatively common. This review of the literature focuses on relevant issues such as maternal safety during nonobstetric surgery in pregnancy, teratogenicity of anesthetic drugs, avoidance of fetal asphyxia, prevention of preterm labor, the safety of laparoscopy, and the need to monitor the fetal heart rate and will finally give a practical approach to manage these patients.

Hypertensive disorders associated with pregnancy are the most common medical diagnoses in pregnancy, occurring in approximately 6% to 8% of pregnancies.¹ Guidelines from the Society of Obstetricians and Gynecologists have classified hypertension of pregnancy into two categories: (1) preexisting or (2) gestational with preeclampsia superimposed on either gestational or preexisting chronic hypertension.² The National High Blood Pressure Education Working Group on High Blood Pressure in Pregnancy classified hypertension as (1) chronic hypertension, (2) preeclampsia-eclampsia, (3) preeclampsia superimposed on chronic hypertension, and (4) gestational hypertension, which is transient during pregnancy, or chronic hypertension identified in the latter half of pregnancy.¹ In 2015, the American College of Obstetricians and Gynecologists Committee on Obstetrics defined a hypertensive obstetric emergency as acute-onset, severe hypertension persistent for 15 minutes or longer.⁴

Gestational hypertension, including preeclampsia, occurs de novo after 20 weeks of gestation. Chronic hypertension is defined as blood pressure $>140/90$ mm Hg either preexisting before the pregnancy or manifesting before the 20th week of gestation. Chronic hypertension is present in up to 22% of women of childbearing age and occurs more commonly in women older than 35 years of age. Approximately 1% of pregnancies are complicated by chronic hypertension, 5% to 6% by gestational hypertension, and 1% to 2% of all pregnancies are associated with preeclampsia. Preeclampsia occurs in 20% to 25% of women with preexisting chronic hypertension.

Preeclampsia, which is usually seen after 20 weeks' gestation, is seen more frequently, although not exclusively, in the older parturient. Preeclampsia is most often observed in younger women (<18 years) and in the older parturient (>35 years). Predisposing factors for the development of hypertension and/or preeclampsia during pregnancy include a family history of hypertension or preeclampsia, preexisting diabetes mellitus, black race, obesity (BMI ≥ 30), vascular or renal disorders, primigravid state, preeclampsia with a previous pregnancy, migraine history, and multiple gestational pregnancies.⁵ Smoking during pregnancy may actually decrease the incidence of hypertension and preeclampsia during pregnancy, although this is controversial.⁶ Hypertensive disorders in pregnancy are a significant leading cause of maternal mortality and morbidity, particularly when preeclampsia is superimposed on preexisting chronic hypertension. A pregnancy-related mortality of 7.6% was reported as a result of hypertensive disorders in the United States from 2006 to 2012.⁷ The risk of recurrent preeclampsia during subsequent pregnancies is approximately 18%. Those who develop preeclampsia earlier during pregnancy have been shown to be at risk for cardiovascular disease later in life.⁷ Women with hypertensive pregnancy disorders are at both immediate and long-term risk for cardiovascular complications.⁸

BLOOD PRESSURE MEASUREMENTS IN PREGNANCY

The definition of hypertension during pregnancy has been controversial in the past. *Hypertension* is now most commonly defined as a blood pressure (BP) greater than 140/90 mm Hg. Recently, there has been a consensus that the degree of increase in systolic (SBPs) and diastolic blood pressures (DBPs) may actually be more important than the baseline values. Many authors now agree that significant hypertension

in pregnancy is defined by an increase of at least 30 mm Hg in the SBP and an increase in the DBP of at least 15 mm Hg. Treatment of a DBP greater than 110 mm Hg or an SBP greater than 160 mm Hg is advocated because of the increase in maternal complications with this degree of hypertension.⁹

Sustained (rather than transient) increases in BP are the key risk factors; accordingly, BP should be measured on at least two separate occasions. BP measurements should be made in a standardized fashion (e.g., with the patient sitting in the same position) at each evaluation. Measurements in the upper arm in the recumbent position may yield false-low values because of aortal and caval compression by the gravid uterus. BP is best recorded with the patient in the sitting position or in the inferior arm in the lateral recumbent position. Many automated blood pressure cuffs are accurate during pregnancy but may underestimate blood pressure measurements in preeclamptic women. Manual BP readings are best suited for this group.

PHYSIOLOGIC CHANGES IN PREGNANCY

Essential to the management of hypertension in pregnancy is an understanding of the normal physiologic changes in cardiac output, vasomotor tone, and systemic BP that occur. During pregnancy, cardiac output increases by 30% to 40% in the second trimester, peaking at about the 24th week of gestation. The increase in cardiac output during the first two trimesters of pregnancy is primarily caused by increased maternal blood volume. Cardiac output plateaus for the remainder of the pregnancy until labor. An increase in cardiac output is seen with each uterine contraction. Cardiac output increases again during the immediate postpartum period after delivery of the fetus and the placenta. It is during this period that cardiac output is highest due to the *autotransfusion effect* (see Chapter 154).

Systemic vascular resistance, and consequently BP, decreases during the second trimester. Increased synthesis of vasodilating prostaglandins may play a role in the regulation of BP and uterine blood flow in pregnancy. In a normal pregnancy, vascular resistance is determined by a proper balance of the effects of vasoconstricting and vasodilating factors, including prostaglandins. This balance may be disturbed in hypertensive states, owing to inadequate prostaglandin synthesis. In pregnancy-related hypertensive states, there is a paradoxical increase in the systemic vascular resistance, compared with pregnancy without hypertension. It is noteworthy that all patients with newly acquired or preexisting hypertension in pregnancy have a relative decrease in DBP during the second trimester, reflecting a relative decrease in systemic vascular resistance. Indeed, BP normalizes during the second trimester in some patients with preexisting hypertension.

CAUSES OF HYPERTENSION IN PREGNANCY

There are multiple causes of hypertension during pregnancy (Box 143-1). The most common hypertensive states are gestational hypertension without the presence of proteinuria, essential chronic hypertension, and preeclampsia (i.e., gestational hypertension with significant proteinuria). This classification is clinically useful to the practitioner, but the risk from systemic hypertension is significant for all three conditions, regardless of the specific cause of high BP. Hypertension

BOX 143-1 Causes of Hypertension in Pregnancy

Pregnancy-induced hypertension (gestational hypertension without proteinuria)
 Essential hypertension
 Preeclampsia (gestational hypertension with proteinuria)
 Primary aldosteronism (Conn's syndrome)
 Renal artery stenosis
 Coarctation of the aorta
 Pheochromocytoma
 Cushing's syndrome

during pregnancy is associated with an increased risk of death for both the mother and fetus. Severe maternal hypertension during pregnancy is associated with placental abruption and intrauterine growth retardation.¹⁰

Preeclampsia is defined as primarily diastolic hypertension that occurs transiently during the pregnancy, usually manifesting after the 20th gestational week, and resolves within 1 to 2 months after delivery. Women who develop preeclampsia have a high rate of recurrence of hypertension with subsequent pregnancies and often develop chronic hypertension at a later time.

Essential chronic hypertension (i.e., hypertension that was present before the pregnancy, whether diagnosed or undiagnosed) persists in the postpartum period and accounts for approximately one-third of all cases of hypertension during pregnancy. Essential chronic hypertension may manifest during the first 20 weeks of pregnancy. Women who develop hypertension without proteinuria in the last trimester of pregnancy may have essential hypertension, either unmasked or precipitated by the pregnancy. In these cases of *de novo* presentation of hypertension, care must be exercised to rule out other nonpregnancy-related causes of hypertension, such as renal artery stenosis, polycystic kidneys, glomerular or interstitial renal disease, pheochromocytoma, coarctation of the aorta, primary aldosteronism, Cushing's syndrome, hyperthyroidism, and hyperparathyroidism. Previously undiagnosed essential chronic hypertension is a consideration, particularly in older multiparous women. As the age of parturients has increased, the incidence of essential hypertension in pregnant women has also increased. For some patients, the initial diagnosis of hypertension may be made during a routine prenatal visit with an obstetrician. For some patients, this prenatal visit is their first encounter with a physician as an adult. Essential hypertension should be suspected if there is a family history of hypertension, diabetes, or obesity. If there is a suspicion of preexisting essential hypertension, cardiac echocardiography should be performed to evaluate for left ventricular hypertrophy, which would suggest that hypertension has been a problem for an extended period. If BP extremes are avoided with treatment, there is no significant worsening of maternal and perinatal outcomes for pregnant patients with essential hypertension. Complications related to intrapartum hypertension (e.g., placenta previa, placental abruption, and preeclampsia) are less likely with judicious treatment of elevated BP. Patients with essential hypertension have not been shown to have a higher incidence of preeclampsia, particularly if the BP is well controlled. In general, mortality and morbidity are not increased in patients with uncomplicated mild chronic hypertension. However, morbidity and mortality are both increased in those patients with severe uncontrolled hypertension, and this is further complicated by superimposed preeclampsia.¹¹

■ PATHOLOGY OF PREECLAMPSIA

Preeclampsia is a pregnancy-related multisystem disease process that usually occurs after the 32nd week of gestation. Systemic hypertension and significant proteinuria (i.e., 0.3 g or greater in a 24-hour urine collection) are invariably present. Clinical onset is usually characterized by rapid weight gain associated with generalized edema, followed by onset of hypertension or proteinuria or both. The incidence of

preeclampsia in the United States ranges from 5% to 7%. The highest frequency occurs in young primigravidas, and the second highest incidence is in older multiparous women, a group that has a higher maternal mortality rate than the young primigravidas. The incidence is higher in patients with preexisting hypertension or renal vascular disease, and the symptoms may present earlier than the 32nd gestational week in these patients. Diastolic hypertension is most often seen in association with preeclampsia. It is less common to record SBP values greater than 160 mm Hg. If the SBP is greater than 200 mm Hg, the clinician should consider the possibility of underlying essential hypertension, which may be superimposed on the preeclamptic state. Since preeclampsia is a multisystem disease process, it may imitate or mask other pathologic conditions, and a thorough investigation to rule out other coexisting pathologies should be carried out.¹² Familial prevalence of preeclampsia has been reported.^{13,14} In some cases, preeclampsia manifests 1 to 7 days after delivery.^{15,16} Most commonly, if preeclampsia is present during the postpartum period, it manifests as the HELLP syndrome, a severe variant of the preeclamptic spectrum of diseases.¹⁷ This syndrome always includes some, if not all, of the following features: microangiopathic hemolytic anemia (H), elevated liver enzymes (EL), and low platelets (LP). The syndrome can develop without substantial BP changes or with no significant changes compared with BP readings taken during the pregnancy.

A significant elevation of BP in the second trimester is associated with an increased risk of preeclampsia later in the pregnancy.¹⁸ One-third of pregnant women with mean arterial pressures greater than 90 mm Hg in the second trimester develop preeclampsia later during pregnancy. Only 2% of women with mean arterial pressures less than 90 mm Hg develop preeclampsia. Relatively mild hypertension early in pregnancy, which might be ignored in nonpregnant patients, should not be overlooked or dismissed in the parturient. As many as 25% of all pregnant women have slightly elevated BPs in the last month of pregnancy, but the incidence of preeclampsia is also highest during this period. Accordingly, clinicians must remain vigilant when faced with new-onset hypertension and look for other signs and symptoms that might suggest the presence of the preeclamptic syndrome.

The exact pathogenesis of preeclampsia is still unknown, although it is believed to be related to endothelial cell injury and dysfunction that occurs in most maternal organs as a result of toxic substances released from a poorly perfused placenta. Genetic and immunologic factors also have been implicated in the pathogenesis of preeclampsia.^{19,20} The generalized vasospasm that occurs in preeclampsia is responsible for many of the organ-specific signs and symptoms apparent in this multisystem disease. Widespread vasospasm is associated with increased circulating levels of vasoconstrictors, increased sensitivity to angiotensin II, and decreased levels of vasodilators. An imbalance in circulating angiogenic factors is emerging as a prominent mechanism that mediates endothelial dysfunction and the clinical signs and symptoms of preeclampsia.²¹ There is an imbalance in the ratio of prostacyclin to thromboxane production that contributes to the pathogenesis of preeclampsia, although preeclampsia is not simply a state of prostacyclin deficiency. This idea has prompted studies of low-dose aspirin to prevent development of preeclampsia. Duley et al. reviewed 59 trials involving 37,560 women that examined the use of antiplatelet agents in preeclampsia. Antiplatelet agents, including low-dose aspirin showed moderate benefits when used for the prevention of preeclampsia and its consequences, decreasing preterm births, fetal and neonatal deaths, and small-for-gestational age babies. However, they recommended that further information would be required to assess which women are most likely to benefit, when treatment is best started, and at what dose.²² The maternal organs most affected in preeclampsia are the kidneys, brain, liver, and hematologic system. Despite a lack of understanding of the exact pathogenesis of preeclampsia, significant improvements in the identification of the disease, monitoring, and management of these complex cases has improved perinatal and maternal morbidity and mortality. If vasospasm affects the uteroplacental bed, the incidence of intrauterine growth retardation, stillbirths, and neonatal deaths increases.²³

Peripheral edema is a common symptom and complaint of pregnant women that cannot be ignored, because it may herald the onset of preeclampsia. The majority of women with preeclampsia presents with generalized edema, and significant weight gain is the first symptom. However, since peripheral edema is a ubiquitous symptom during pregnancy, it is no longer considered a hallmark trait of preeclampsia. Preeclampsia is often manifested initially by peripheral edema that is usually accompanied by a gradual increase in BP. Sodium retention is partly responsible for edema formation and hypertension. In normal pregnancy, the glomerular filtration rate increases by as much as 50%. There is a concomitant increase in sodium reabsorption by the renal tubules and a 60% to 80% increase in renal blood flow. Renal blood flow increases because of the increase in cardiac output and a decrease in renal vascular resistance. In preeclampsia, sodium retention is caused by a decrease in the glomerular filtration rate, possibly resulting from a vasospasm of the renal vasculature, commonly seen in preeclampsia. Renin and aldosterone secretion decrease in patients with preeclampsia, probably as a result of extracellular volume expansion and associated edema. The exact cause of the decreased activity of these factors is unknown, but it may be related to decreased renal prostaglandin synthesis, increased systemic BP, or the expansion of extracellular volume. In spite of the decreased levels of renin and aldosterone, sensitivity to angiotensin II is increased, a factor that may play a role in the pathogenesis of hypertension in preeclampsia.²⁴ Vascular maladaptation with increased vasomotor tone, endothelial dysfunction, and increased sensitivity to angiotensin II and norepinephrine in preeclampsia may be explained on the basis of angiotensin II-mediated mechanisms. Although sodium retention occurs in preeclampsia, blood volume actually can be diminished compared with that in normotensive pregnant patients.²⁵ Plasma volume contracts as extracellular fluid is preferentially shifted from the vascular space to the interstitium. However, the decrease in plasma volume does not indicate volume depletion in patients with preeclampsia. In contrast to hypovolemic patients, cardiac output is increased and central venous and pulmonary capillary wedge pressures are normal to high in patients with preeclampsia.²⁶ These data guide the management of preeclampsia, because efforts should be directed to control BP rather than injudicious volume resuscitation.

Hyperuricemia in preeclampsia occurs at least in part because of decreased renal excretion of uric acid. However, the development of hyperuricemia frequently predates increases in serum blood urea nitrogen and creatinine, suggesting that other mechanisms are involved as well. Hyperuricemia has been used as a marker of severity of preeclampsia, and it is a risk factor for fetal mortality.²⁷

CLINICAL PRESENTATION OF PREECLAMPSIA

The severity of illness is defined as mild, moderate, or severe depending on the presenting signs and symptoms and associated comorbidities. Since the nature of the process is a multisystem, preeclampsia may manifest with a wide spectrum of organ-specific abnormalities in addition to the general findings of edema, hypertension, and proteinuria. The pathologic abnormalities associated with preeclampsia are not necessarily secondary to hypertension, and thus, the severity of preeclampsia does not always correlate with the degree of BP elevation.¹⁸ BP elevations are classified as mild, moderate, or severe. Hypertension in preeclampsia may result from increases in systemic vascular resistance and cardiac output.

In mild preeclampsia, SBP is 130 to 140 mm Hg and DBP is 80 to 95 mm Hg. Peripheral edema is minimal, and there is a lack of associated visual or cerebral symptoms. In moderately severe preeclampsia, the SBP may increase to as high as 150 to 160 mm Hg, and the DBP can be as high as 110 mm Hg. An increase in SBP of 25 mm Hg or more and an increase in DBP of 15 mm Hg or more suggests the presence of moderate to severe preeclampsia. Peripheral edema, hyperreflexia, and visual symptoms are present with moderately severe preeclampsia. In severe forms of preeclampsia, the SBP is greater than

160 mm Hg, and the DBP is 110 mm Hg or greater. In severe preeclampsia, there are signs of multiple organ system involvement. Pulmonary, cardiac, renal, and neurologic disturbances may be present. Severe renal involvement in preeclampsia leads to glomeruloendotheliosis, which manifests as marked proteinuria (excretion of greater than 5 g protein daily). Oliguria (urine output less than 500 mL/day) is also common, and the serum creatinine concentration is usually greater than 1.6 mg/dL. Acute renal failure is relatively rare, although clinical evidence of renal involvement in preeclampsia significantly increases perinatal mortality.²⁸ Hepatic involvement is manifested by epigastric or right upper quadrant pain with elevated circulating levels of bilirubin and transaminases. Severe preeclampsia itself is the most common cause of hepatic tenderness and liver dysfunction in pregnancy.²⁹ Severe hepatic pathology can result in subcapsular hematomas and lacerations that may require surgical intervention. Neurologic changes may include persistent headaches, visual disturbances, focal neurologic deficits, and severe hyperreflexia with or without clonus. Computed tomography of the brain may exhibit cerebral edema, especially in the occipital region.

Severe preeclampsia associated with central nervous system irritability, manifesting as generalized tonic-clonic seizures not caused by other cerebral pathology, is defined as *eclampsia*.³⁰ Eclampsia can occur without significant hypertension or proteinuria. Cardiovascular and respiratory changes can manifest as pulmonary edema, resulting from iatrogenic fluid overload; acute systolic left ventricular failure; or diastolic left ventricular dysfunction secondary to chronic essential hypertension. Pulmonary edema may also result from increased capillary permeability or from a decrease in colloid osmotic pressure that occurs to some extent during normal pregnancy but can be accentuated by preeclampsia.³¹ Hematologic disturbances consist of thrombocytopenia, disseminated intravascular coagulation, and hemolysis.

It is unknown whether preeclampsia leads to persistent chronic hypertension after delivery, although it seems that this is unlikely. Nevertheless, an episode of preeclampsia may identify a subgroup of women with an increased risk of the eventual development of essential hypertension at a later time. In a recent study, women with preeclampsia had an increased risk of death due to cardiovascular disease later in life, independent of other measured risk factors.³² These findings reinforced previously reported recommendations that a history of preeclampsia should be used to target women at risk for cardiovascular disease. Debate continues as to whether the presence of preeclampsia or the duration of the disease process may be responsible for influencing factors that later lead to the development of essential hypertension. Women who develop preeclampsia superimposed on previously undiagnosed essential hypertension or underlying renal disease are predisposed to the later development of essential hypertension.

OTHER CAUSES OF HYPERTENSION IN PREGNANCY

Some of the less common causes of hypertension are listed in [Box 143-1](#).

Primary aldosteronism in pregnant women has been reported but is uncommon. The treatment of hypertension in these patients is directed toward medical management during the pregnancy and postpartum operative intervention if an adenoma is present.

Renal artery stenosis can be associated with preeclampsia. Medical therapy with antihypertensive agents is recommended. Although ideal therapy for these patients would include angiotensin-converting enzyme (ACE) inhibitors, these agents are contraindicated during pregnancy, and other alternatives must be employed.³³

Coarctation of the aorta is a rare cause of hypertension. It may be previously undiagnosed and then initially diagnosed during a patient's first pregnancy. It can be associated with preeclampsia. The greatest risk to these patients is aortic rupture due to cystic medial necrosis of the aortic wall. This risk is amplified because the normal physiologic changes of pregnancy place further stress on the abnormal aorta. Increases in BP, cardiac output, and the strain of labor with

contractions can increase this risk. Aggressive medical management with antihypertensive medications, including β -adrenergic blockers, improves the outcome of these high-risk patients.

Pheochromocytoma is a rare cause of hypertension, but patients have a poor outcome if the tumor is not diagnosed and treated. These patients can present with nausea, vomiting, profuse diaphoresis, severe headache, generalized weakness, palpitations, and seizures. The immediate causes of sudden death are secondary to pulmonary edema, cerebral hemorrhage, and cardiovascular collapse. Since there is a risk of significant morbidity and mortality to both mother and fetus, it was previously recommended that immediate surgical intervention be carried out during pregnancy. Currently, most experts advocate medical therapy with α - and β -adrenergic blockade during pregnancy and tumor removal after delivery.

■ GENERAL TREATMENT PRINCIPLES

The benefits of a well-balanced low-salt diet and exercise have been shown to decrease the incidence and severity of hypertension. Bennett conducted a retrospective analysis of women who had prior bariatric surgery before becoming pregnant. These patients had lower rates of hypertensive disorders in subsequent pregnancies.³⁴ Previously, some experts were concerned that aggressive management of hypertension in pregnancy might be detrimental, perhaps because hypertension improved the uterine blood flow. These concerns appear to be unfounded, because later studies showed that uterine blood flow either increases or shows no change after hypertension is controlled. Nevertheless, caution must be exercised to ensure that the treatment of hypertension during pregnancy does not induce hypotension, which adversely affects maternal hemodynamics and compromises fetal well-being. There is a significant correlation between maternal BP control and fetal morbidity, and evidence now suggests that antihypertensive treatment for severe hypertension results in an improved perinatal outcome. The development of mild hypertension or preeclampsia at or near term is associated with minimal maternal and neonatal complications. However, the onset of severe gestational hypertension and/or severe preeclampsia early in gestation is associated with significant maternal and perinatal complications.³⁵ General recommendations for management and monitoring of hypertension in pregnant patients include the stabilization and treatment of acute changes in BP. Specific goal-directed therapy is indicated for various organ system abnormalities that may be present, particularly in those patients with moderate to severe preeclampsia. If proteinuria is not present and there is no suspicion of preeclampsia, conservative management on an outpatient basis is usually adequate. Immediate hospitalization with bed rest is recommended for patients presenting with proteinuria if there is a high index of suspicion for the diagnosis of preeclampsia.

■ ANTIHYPERTENSIVE DRUG THERAPY

There is now an extensive pharmaceutical armamentarium available for the treatment of hypertension in pregnancy. In 1979, the U.S. Food and Drug Administration (FDA) established categories for all drugs with potential and actual adverse effects on the fetus.³⁶ Although helpful to the clinician, these categories most often do not reflect current scientific knowledge regarding specific teratogenic effects of the drugs.³⁷

The FDA categories are listed in Table 143-1. Most antihypertensive drugs used during pregnancy are classified as category C. Thiazide diuretics, prazosin, and α -methyl dopa are designated as category A, and metoprolol is a category B agent. Since most antihypertensive drugs are used later in pregnancy, the potential teratogenic effects of these drugs are not usually a major concern. However, if treatment is initiated for patients with preexisting essential hypertension or early-onset gestational hypertension, teratogenic effects must be considered when choosing antihypertensive drugs. It may be necessary to change the antihypertensive therapy early in pregnancy, if the patient is taking drugs that could increase the risk of fetal abnormalities.

TABLE 143-1

FDA Categories of Fetal Drug Toxicities

| CATEGORY | DESCRIPTION |
|----------|--|
| A | Controlled studies in pregnant women have not demonstrated any risk to the fetus in the first trimester. These drugs are considered to be relatively safe for use during pregnancy. |
| B | No known specific risks are associated with use of the drug in pregnancy, but controlled human studies are lacking. If adverse effects were shown in animal reproduction studies, these were not confirmed in controlled human trials. |
| C | Studies in women and animals are not available, or studies in animals have revealed adverse effects on the fetus. Most new drugs fall into this category. These drugs should be given only if the potential benefit justifies the potential risk to the fetus. |
| D | These drugs have shown a definite fetal risk in controlled human trials. However, their use may be necessary during pregnancy, and a risk-benefit assessment needs to be considered for the use of these agents. |
| X | These drugs have shown a definite risk to the fetus, and their use is contraindicated because the potential risks to the fetus outweigh the potential benefits. |

FDA, U.S. Food and Drug Administration.

The goal of hypertensive therapy in pregnancy is the prevention of maternal complications such as intracerebral hemorrhage, stroke, and decompensated heart failure. There are no convincing data to determine the optimal BP goal with drug therapy. There is also disagreement concerning the proper normal values for BP during pregnancy, but most agree that acute treatment is mandated if (1) the SBP is greater than 160 mm Hg or the DBP is 105 mm Hg or greater or (2) if the SBP is more than 30 mm Hg greater than the baseline value or the DBP is more than 15 mm Hg greater than the baseline. For women with preexisting chronic hypertension, a blood pressure of more than 160/100 should be targeted. If acute and urgent drug therapy management is required, some patients may need to be hospitalized, depending on their compliance with drug therapy and the urgency of lowering the BP based on concomitant organ system involvement. For patients presenting with SBP 140 mm Hg or higher and DBP 90 mm Hg or higher, urgent drug therapy should be implemented if there is concurrent evidence of symptoms, underlying essential hypertension, or end-organ involvement. If the patient presents after the 24th gestational week and fetal viability is ascertained, both cardiac and fetal telemetry may be required. For patients presenting with SBP less than 140 mm Hg and DBP less than 90 mm Hg and no evidence of significant proteinuria, management and treatment can be provided on an outpatient basis, with frequent office visits and close maternal and fetal assessments. If the hypertension is refractory to standard therapy, hypertension worsens despite adequate drug therapy, or the suspicion of preeclampsia arises, then immediate hospitalization is recommended.

Conservative drug therapy is advocated for moderately severe preeclampsia, but the treatment of choice for severe preeclampsia and associated end-organ involvement is the immediate delivery of the fetus. Delay in delivery for patients with severe preeclampsia and end-organ involvement can result in serious maternal and fetal complications. If the fetus is of mature gestational age, factors influencing the decision to deliver are dependent on the progression of the disease process, assessment of fetal lung maturity, and the status of the cervix. The conservative management of preeclamptic patients at a gestational age less than 24 weeks is associated with serious maternal complications, and termination of the pregnancy should be considered. For patients at 28 to 32 weeks of gestation, conservative management with

vigilant monitoring and assessment should be performed in a hospital setting. There is a lack of evidence from the limited trials performed to recommend either early delivery or expectant care for women with severe preeclampsia before 34 weeks of pregnancy.³⁸

Updated guidelines from 2015 from the American College of Obstetricians and Gynecologists Committee on Obstetric Practice⁴ recommend that:

- In addition to parenteral hydralazine and labetalol, oral nifedipine and/or oral labetalol (200 mg) may be considered as a first-line therapy, particularly if there is no IV access.
- Parenteral labetalol should be avoided in women with asthma, heart disease, or congestive heart failure.
- Magnesium sulfate is not recommended as an antihypertensive agent but is the drug of choice for seizure prophylaxis in severe preeclampsia and for controlling seizures in eclampsia.
- Although sodium nitroprusside can be used for treatment in emergent situations, there is a risk of cyanide and thiocyanate toxicity in the mother and fetus and increased intracranial pressure with potential worsening of cerebral edema in the mother.

During pregnancy, the clinician must decide when to use antihypertensive medications and what level of BP to target. The choice of antihypertensive agents is more limited in pregnancy, since not all available antihypertensive drugs have been adequately evaluated in pregnant women, and some agents are contraindicated.³⁹ A first-line drug still used today in pregnant patients, although less commonly in the general populace, is oral α -methyl dopa, a central α_2 -adrenergic agonist. Historically this has been a first-line drug of choice for many obstetricians in the past, and there has been little evidence to convince them otherwise. The starting dose is 250 mg orally 2 to 3 times a day for the first 48 hours of treatment. Dosing can be increased every 2 days until the desired BP level is achieved. The maximum daily dose is 4 g. β -Adrenergic blocker therapy with oral labetalol, a combined α - and β -adrenergic antagonist, has become popular as a single-agent antihypertensive. The recommended initial dose is 100 mg orally twice daily. The dose can be increased as indicated, either semiweekly or weekly, and the maintenance dose is usually 200 to 400 mg administered twice daily. The benefits of the β -adrenergic blockade make this an attractive drug for parturients with underlying chronic essential hypertension and possible cardiac and vascular involvement. Diuretics also may be used, although care must be exercised to prevent excessive fluid loss, which can exacerbate the decrease in blood volume associated with preeclampsia. As mentioned previously, ACE inhibitors and angiotensin II receptor antagonists should be avoided intrapartum because these agents can increase perinatal morbidity and mortality.

For acute and emergent drug therapy for severe hypertension, intravenous (IV) antihypertensive drugs should be used; IV infusions are particularly attractive because they provide rapid control of BP and can be titrated easily. Intravenous hydralazine, a direct arteriolar vasodilator, remains the standard for many obstetricians, although other drugs may be preferable since hydralazine may decrease BP precipitously.⁴⁰ Excessive lowering of BP is a particular problem when hydralazine is administered to preeclamptic patients with contracted blood volume. If hydralazine is used, it should be given as 5- to 10-mg IV boluses every 15 to 30 minutes until BP is controlled. Onset of the hypotensive effect is 10 to 20 minutes, and duration of action is about 8 hours. Infusions of hydralazine are difficult to titrate and may be associated with increased incidence of fetal distress.

Intravenous labetalol, a nonselective β - and α -adrenergic receptor blocker, is also commonly used for the acute management of hypertension. Labetalol rapidly decreases the BP but not at the expense of uteroplacental blood flow. Labetalol crosses the placenta but rarely causes significant neonatal bradycardia. An initial IV bolus of 10 or 20 mg should be given, followed by boluses of 40 to 80 mg at 10- to 15-minute intervals as needed to control hypertension. Labetalol also can be given by continuous IV infusion; the usual dose is 1 to 4 mg/min. Contraindications to the use of labetalol are the same as those for other β -adrenergic antagonists, notably heart block and acute asthma.

TABLE 143-2

Antihypertensive Drugs Commonly Used in Pregnancy

| TYPE | AGENTS |
|----------------------|-----------------------|
| Oral | α -Methyl dopa |
| Labetalol | |
| Clonidine | |
| Diuretics | |
| Parenteral | Labetalol |
| Hydralazine | |
| Sodium nitroprusside | |
| Nitroglycerin | |

Sodium nitroprusside is a potent arterial and venous vasodilator that quickly decreases the BP. Rapid titration with a continuous IV infusion can be instituted starting at a dose of 0.25 to 0.5 μ g/kg/min and adjusted every few minutes and titrated to effect. Invasive arterial monitoring is often recommended in conjunction with its use. As with all potent vasodilators, care must be taken when using sodium nitroprusside, because patients with volume depletion may be particularly sensitive to its effects. Despite a paucity of data, concern regarding the risks of fetal cyanide toxicity prompts some practitioners to avoid using this drug in pregnant patients. Careful attention to dosing and duration of use should minimize the risk of toxicity.

Other less frequently used agents include IV nitroglycerin, oral clonidine, and β -adrenergic blockers other than labetalol. Intravenous nitroglycerin is easily titrated and is especially attractive for the management of patients with pulmonary edema. However, its antihypertensive potency is somewhat limited. Oral clonidine, a centrally acting α_2 -adrenergic agonist, is an effective antihypertensive drug, but concerns about the risk of rebound hypertension after cessation limit its use.

There remains considerable debate concerning the use of β -adrenergic blockers in pregnancy because of the potential risks of fetal bradycardia and a decrease in perfusion to the uteroplacental bed. Beta-blockers have been used during pregnancy without evidence of teratogenic effects. Although there is limited experience, they are considered as indicated in pregnant women with hypertension, mitral stenosis with pulmonary hypertension, coarctation of the aorta, ischemic heart disease, supraventricular and ventricular arrhythmias, and can be continued during delivery.^{1,41,42} Esmolol has been used widely for heart rate control in pregnancy, but its efficacy is limited as an antihypertensive agent.

Antihypertensive drugs commonly used during pregnancy are listed in Table 143-2.

MANAGEMENT OF HYPERTENSION DURING LABOR AND DELIVERY

Management of hypertension during labor and delivery is directed toward avoiding acute and maternal complications. Antihypertensive drug therapy with a judicious use of IV fluids is of paramount importance to avoid unnecessary complications. Postpartum monitoring is advocated for high-risk, chronically hypertensive patients. Hypertension associated with preeclampsia usually resolves spontaneously within a few weeks after delivery. These patients are at risk for the development of acute complications, such as hypertensive encephalopathy, pulmonary edema, and acute renal failure. The choice of antihypertensive medications or the doses used may have to be adjusted after delivery, and minute amounts of all antihypertensive agents are found in breast milk. Although limited data are available, adverse perinatal effects have not been observed with the more commonly used drugs, such as α -methyl dopa, hydralazine, and the various α -adrenergic blockers.

KEY POINTS

1. Hypertensive disorders associated with pregnancy are not uncommon and can either predate the pregnancy or be precipitated or unmasked by the pregnancy.
2. Women with a prenatal history of diabetes mellitus, renal disease, vascular disease, or a family history of hypertension are predisposed to developing hypertension during pregnancy.
3. Treatment is recommended if the systolic blood pressures (SBPs) are 160 mm Hg or higher, or the diastolic blood pressures (DBPs) are 110 mm Hg or higher, or with lower BPs if the patient is symptomatic.
4. BP measurements should be consistently taken in either the sitting position or in the inferior arm in the lateral recumbent position with each evaluation.
5. Cardiac output and blood volume are dramatically increased during pregnancy, and there is a decrease in systemic vascular resistance, particularly during the second trimester. DBP is lowest during the second trimester.
6. Elevated BPs caused by essential hypertension may transiently improve during the second trimester of pregnancy.
7. Consistently elevated SBPs greater than 200 mm Hg should prompt the practitioner to consider undiagnosed chronic hypertension or some of the less common causes of hypertension such as primary aldosteronism, renal artery stenosis, or pheochromocytoma.
8. Preeclampsia most often appears after the 32nd week of gestation and resolves with the delivery of the fetus.
9. Preeclampsia can be superimposed on chronic hypertension.
10. Preeclampsia may initially present after delivery as the HELLP syndrome (*hemolysis, elevated liver enzymes, and low platelets*).
11. Hypertension with BP elevation of 140/90 mm Hg or higher and proteinuria are the principal characteristics of preeclampsia. Edema is no longer a criterion for preeclampsia.
12. Preeclampsia is a multisystem disease. Severe preeclampsia manifests with signs and symptoms of end-organ involvement.
13. The antihypertensive drugs most frequently used in pregnancy have not been associated with significant fetal abnormalities.
14. First-line antihypertensive drugs for moderate hypertension are oral α -methyldopa and oral labetalol.
15. Parenteral antihypertensive agents are used for more severe elevations of BP. The agents most commonly employed are labetalol, hydralazine, and sodium nitroprusside.
16. Caution should be exercised with the administration of hydralazine, particularly in patients with decreased plasma volume.
17. Most forms of gestational hypertension resolve in the postpartum period.

ANNOTATED REFERENCES

AACE Hypertension Task Force. American Association of Clinical Endocrinologists medical guidelines for clinical practice for the diagnosis and treatment of hypertension. *Endocr Pract* 2006;12:193.

In 2006, the American Association of Clinical Endocrinologists (AACE) proposed guidelines for the diagnosis and treatment of hypertension, focusing on identifying and managing hypertension relating to or coinciding with endocrinopathies. These guidelines are based on positive data from randomized clinical trials. They recommended diuretics, beta-blockers, angiotensin-converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs), and calcium channel blockers (CCBs) for treating hypertension in patients, particularly those with diabetes mellitus.

Magee L, Cham C, Waterman EJ, et al. Hydralazine for treatment of severe hypertension in pregnancy: meta-analysis. *BMJ* 2003;327:955.

A meta-analysis was performed to review the outcomes in randomized controlled trials published between 1966 and 2002 that compared hydralazine with other antihypertensive agents for severe hypertension in pregnancy. In 13 trials comparing hydralazine with either nifedipine or labetalol, hydralazine was an effective antihypertensive drug for severe hypertension but was associated with an increased incidence of maternal hypotension, cesarean section, placental abruption, oliguria, adverse effects on fetal heart rate, and lower Apgar scores.

Magee LA, Helewa M, Moutquin J-M, et al. Diagnosis, evaluation, and management of the hypertensive disorders of pregnancy. *J Obstet Gynaecol Can* 2008;30:S1.

These guidelines from the Society of Obstetricians and Gynecologists are a comprehensive review of the different manifestations of hypertension during pregnancy. The guidelines focus on the classification, pathophysiologic features, and management of the hypertensive disorders of pregnancy. The authors classified hypertension of pregnancy into two categories, preexisting or gestational with preeclampsia superimposed on either gestational or preexisting chronic hypertension. Through a combination of evidence-based medicine and consensus, this report updates contemporary approaches to hypertension control during pregnancy.

Seely EW, Maxwell C. Chronic hypertension in pregnancy. *Circulation* 2007;115:e188–e190.

This review describes chronic hypertension during pregnancy. It further describes the complications of chronic hypertension during pregnancy and how chronic hypertension affects both maternal and fetal outcomes.

Sibai B, Dekker G, Kupferminc M. Pre-eclampsia. *Lancet* 2005;359:785.

This is a comprehensive review of preeclampsia with information on epidemiology, pathogenesis, and different treatment modalities. Maternal and perinatal outcomes are also discussed. The authors reviewed findings on the diagnosis and risk factors of preeclampsia and the present status of its prediction, prevention, and management.

During pregnancy, the respiratory system undergoes a number of changes and is subject to functional and anatomic stresses. The critical care provider must remember these changes to appropriately care for the maternal-fetal unit. Although the need for ventilatory support is rare in pregnancy, respiratory insufficiency is still the most common indication in pregnancy for admission to a critical care unit. In this chapter, the unique physiologic changes that occur during pregnancy are addressed, and guidance is provided to critical care specialists who may encounter pregnancies that are complicated by acute pulmonary complications.

PULMONARY PHYSIOLOGY IN PREGNANCY

A number of physiologic changes affect respiration during pregnancy. Normal pregnancy is associated with a 20% increase in oxygen consumption and a 15% increase in metabolic rate. During the first trimester, minute ventilation is increased, while the respiratory rate remains the same. Although one might assume that the lung volume during pregnancy would decrease owing to a rise in the maternal diaphragm, the tidal volume (V_T) is actually increased by 40% over baseline values. The increase in V_T is thought to be due to the increase in circulating progesterone that affects the respiratory center.¹ Arterial blood gas measurements reflect respiratory alkalosis compensated by metabolic acidosis that results in a relatively normal pH. P_{aCO_2} usually ranges from 28 to 32 mm Hg. Functional residual capacity (FRC), residual volume, and total lung volume are decreased near term. Because of this decrease, respiratory distress occurs more rapidly in the gravid than in the nongravid state. The function of the large airways as measured by forced expiratory volume at 1 second (FEV_1), and peak expiratory flow rate (PEFR) is essentially unchanged throughout pregnancy.²

Colloid osmotic pressure is decreased by 20%. This change in hydrostatic pressure results in a propensity for pregnant patients to develop cardiogenic and noncardiogenic pulmonary edema.

Dyspnea on exertion is common, especially in the third trimester of pregnancy, making the diagnosis of respiratory problems more difficult than that in the nongravid state.

Figure 144-1 illustrates the graphic relationship of pulmonary changes.

ASTHMA

Epidemiology

Asthma is one of the most common pulmonary problems in pregnant women; recent studies have reported that approximately 8% are affected.³ The disease is characterized by hyperactive airways leading to episodic bronchoconstriction. The role of inflammatory mediators in the pathogenesis of asthma has become apparent in recent years, leading to the early use of antiinflammatory medications in the treatment of exacerbations.

The cause of asthma is unknown; however, it has been observed that its prevalence in the general population is increasing.

Effects of Asthma on Pregnancy

Asthma may be triggered by environmental allergens, medications, especially aspirin or nonsteroidal antiinflammatory drugs (NSAIDs), or stress.⁴ Most exacerbations are marked by cough, wheezing, and dyspnea. Rapid therapeutic intervention at the time of an exacerbation is imperative to prevent impaired maternal and fetal oxygenation because uncontrolled asthma can increase maternal morbidity. In several studies, even after controlling for confounding variables, adverse pregnancy outcomes are more pronounced in patients with asthma. These include low birth weight, preeclampsia, preterm birth, and stillbirth.^{5,6}

Although historical data have shown an increase in perinatal death and low birth weight,⁷ Fitzsimmons and colleagues observed low birth weight in only those patients treated for status asthmaticus.⁸ In addition, Schatz and colleagues noted that intrauterine growth restriction was directly related to lung function as measured by FEV_1 .⁹

Effect of Pregnancy on Asthma

Numerous studies have observed that the course of asthma may be affected by pregnancy. Gluck et al. found that, on average, asthma improved in 36% of women during pregnancy, remained unchanged in 41%, and worsened in 23%.¹⁰ Schatz et al., in an analysis of 366 pregnancies in which patient status was followed by objective criteria, found that asthma improved in 28% of women, remained unchanged in 33%, and worsened in 35%. Fifty-nine percent of the patients had similar asthma control in successive pregnancies.¹¹

Fetal sex may influence asthma in pregnancy. In one study, mothers who gave birth to boys were more likely to report improved asthma symptoms.¹² Dodds and colleagues found that the use of medications to treat asthma was less common in mothers of boys.¹³ While a number of hypotheses have been proposed, including alterations in progesterone levels and the role of leukotrienes, changes in not one of these mediators can explain the varied course of pregnant asthmatics.¹⁴

Management

The National Asthma Education and Prevention Program issued specific guidelines regarding asthma treatment. In 1993, the Working Group on Asthma and Pregnancy established criteria for diagnosis and treatment among the gravid population (Fig. 144-2).¹⁵

The goals of treatment during pregnancy are to control exacerbation and prevent status asthmaticus, thereby reducing maternal and fetal hypoxemia. The initial step in treatment involves monitoring pulmonary function, and FEV_1 is the single best measure. A physical examination and chest radiography are poor measures of disease severity. A portable hand-held peak flow meter gives a quick, accurate assessment by measuring the PEFR. Most authorities believe that airways remain essentially unchanged throughout pregnancy; therefore, every patient with asthma should be given a peak flow meter and be educated in its use. The patient should obtain a baseline PEFR during a quiescent period. The severity of disease is determined by the occurrences of exacerbations and changes in FEV_1 and

FIGURE 144-1 ■ Respiratory changes in pregnancy.

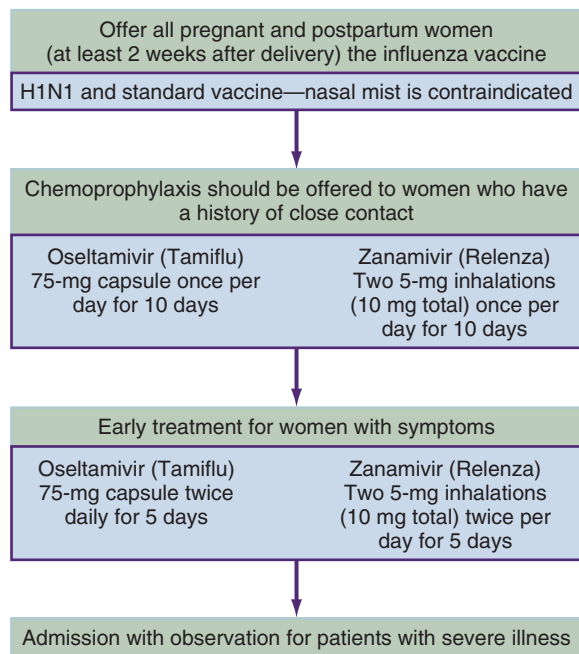

FIGURE 144-2 ■ Treatment during pregnancy.

PEFR. The PEFR can be used as a guide to refer the patient for emergency care.

Pharmacologic therapy is the mainstay of asthma treatment. Most drugs used in the treatment of asthma are thought to be safe in pregnancy. Inhaled β -agonists are the most frequently used in asthma treatment. A prospective study of inhaled β -agonists in 259

pregnancies showed no change in the rate of congenital malformation, perinatal mortality, low birth weight, or complications of pregnancy.¹⁶ There is little role for the use of oral β -agonists, which may cause more adverse systemic symptoms and are not more effective than inhaled drugs.

Inhaled corticosteroid therapy remains the mainstay of antiinflammatory treatment of asthma. Corticosteroids have also been advocated as first-line therapy in patients with mild asthma.¹⁷ Studies have demonstrated that with asthma, those taking an inhaled corticosteroid were four times less likely than their nontreated counterparts to suffer an exacerbation.¹⁸ Another randomized study noted that there was a 55% reduction in readmission rates due to acute asthma in patients using inhaled beclomethasone.¹⁹ Inhaled corticosteroids can increase the effectiveness of β -adrenergic agents by inducing the formation of new β receptors. Because beclomethasone is the most studied of the inhaled corticosteroids in pregnancy, it is recommended as first-line therapy.¹⁵ However, if patients are well controlled on other corticosteroid preparations, it is suggested they be continued on their current medication because all inhaled corticosteroids are labeled by the U.S. Food and Drug Administration (FDA) as pregnancy class C. Other antiinflammatory medications used in the treatment of asthma (e.g., cromolyn sodium and nedocromil sodium) appear to be less effective than inhaled corticosteroids in reducing asthma symptoms.

Systemic corticosteroids should be reserved for the periodic treatment of acute asthma exacerbations. Chronic oral corticosteroid therapy may increase the risks of gestational diabetes mellitus, preterm labor, low-birthweight infants, and preeclampsia; however, it is evident that the benefits of controlled severe asthma outweigh the potential risks to the mother and fetus.

Intravenous corticosteroids have no increased benefits over oral corticosteroids in the treatment of acute exacerbations.²⁰ Methylprednisolone, hydrocortisone, and prednisone are safe for use in pregnancy, unlike betamethasone or dexamethasone, because very little active drug crosses the placenta.

BOX 144-1 Treatment of Asthma in Pregnancy**MILD ASTHMA**

Characterized by FEV_1 or $PEFR \geq 80\%$

Brief (<1 hour) exacerbations

Treatment: inhaled β_2 -agonist

MODERATE ASTHMA

Characterized by FEV_1 or $PEFR$ range from 60% to 80%

Exacerbations more than twice per week; exacerbations may last for several days, and occasional emergency care needed

Treatment: inhaled corticosteroids and inhaled β_2 -agonist

SEVERE ASTHMA

Characterized by FEV_1 or $PEFR < 60\%$ of baseline

Continuous symptoms, limited activity, frequent exacerbations and nocturnal symptoms, occasional hospitalization and emergency treatment needed

Treatment: inhaled corticosteroids, inhaled β_2 -agonist, sustained-release theophylline; oral corticosteroid taper for active symptoms

Leukotriene pathway moderators have been shown to improve pulmonary function, as measured by FEV_1 .²¹ Zafirlukast and montelukast are rated as FDA category B; however, these drugs have not been frequently used in pregnancy, and their role is undetermined.

The treatment of asthma requires providing patient education in the preconceptional period and during the pregnancy for optimum outcome. Box 144-1 shows a suggested schematic for the treatment of asthma in pregnancy.

STATUS ASTHMATICUS

Status asthmaticus is a rare complication in pregnancy. Diagnosis is established by a Pao_2 of less than 70 mm Hg, a $Paco_2$ of greater than or equal to 35 mm Hg, or a measured expiratory flow of less than 25% of expected. Because of impending respiratory failure, these patients should be managed in a critical care unit. Aggressive treatment of status asthmaticus is mandatory to protect the mother and fetus. Maternal mortality may be as high as 7% and fetal mortality as high as 11% despite adequate treatment. Epinephrine is not contraindicated in pregnancy during a respiratory emergency. Criteria for intubation in gravida with status asthmaticus include (1) inability to maintain a Pao_2 of greater than 60 mm Hg despite supplemental oxygen; (2) inability to maintain a Pco_2 of less than 40 mm Hg; (3) evidence of maternal exhaustion, with worsening acidosis ($pH < 7.2$) despite intensive bronchodilator therapy; and (4) altered maternal consciousness.¹⁵

When traditional treatment proves to be ineffective, a number of therapies have been reported to be beneficial. The use of a helium-oxygen mixture that has been reported to be effective in studies in nonpregnant women has been used safely in pregnancy.²²

PULMONARY EDEMA

Pulmonary edema can be divided into two categories during pregnancy. *Cardiogenic pulmonary edema* is the result of high intravascular pressures creating a hydrostatic pressure gradient that results in extravasation of fluid into lung tissues despite the integrity of normal lung microcirculation. *Noncardiogenic pulmonary edema* is the result of a leaky pulmonary capillary bed despite normal intravascular pressures. During pregnancy, the distinction between these two types of edema may be blurred owing to disease states that exacerbate the hypooncotic state of pregnancy.

Etiology

There are a number of causes of pulmonary edema in pregnancy. Some are pathologic in their process; others are due to idiopathic causes. One

BOX 144-2 Treatment in Patients with Pulmonary Edema

1. Determine the etiology, stop fluids, tocolysis, etc.
2. Treat with a diuretic (the author prefers furosemide in increments of 10- to 20-mg IV push).
3. Consider the use of morphine sulfate for patient comfort, 1- to 2-mg IV push q 2-3 h.
4. Proceed with hemodynamic monitoring if the patient does not rapidly respond to the above measures.
5. Consider intubation and mechanical ventilation with positive pressure for those patients with noncardiogenic pulmonary edema and those patients with cardiogenic pulmonary edema who need further support.

of the most common associations with pulmonary edema during pregnancy is hypertensive disease. In patients with hypertensive disease, pulmonary edema may be cardiogenic due to fluid overload or left ventricular dysfunction or noncardiogenic due to decreased oncotic pressure.

Another common cause of pulmonary edema in pregnancy is tocolytic therapy. Most cases described have resulted from the intravenous use of beta sympathomimetics. The use of magnesium sulfate therapy as well as the use of corticosteroids in association with tocolysis for preterm labor have been shown to exacerbate the condition. The incidence of edema is increased in multiple gestations and in patients with subclinical infection.

Other causes of acute pulmonary edema in pregnancy include amniotic fluid embolism, aspiration, and the need for massive transfusion after hemorrhage.²³

Treatment

The treatment of pulmonary edema during pregnancy depends on its etiology. The cause is best determined by the use of pulmonary artery catheterization and measurement of pulmonary capillary wedge pressure. Although all patients may not require this intervention, it is recommended in patients in whom the clinical picture may be unclear (e.g., those with hypertensive disease) and in those who do not respond to standard diuretic therapy.

For patients who do not improve rapidly with diuretic therapy, intubation and ventilation with positive pressure is recommended. In addition to the use of diuretic therapy, reduction of preload and afterload may be achieved by the use of vasodilators such as nitrates, hydralazine, or calcium channel blockers. All are safe for use in pregnancy.

Box 144-2 shows a guide for the treatment of patients with pulmonary edema.

ACUTE RESPIRATORY DISTRESS SYNDROME**Etiology**

The causes of acute respiratory distress syndrome (ARDS)²⁴⁻²⁷ in pregnancy include preeclampsia, sepsis, aspiration, pyelonephritis, intrauterine infections, acute fatty liver of pregnancy, and amniotic fluid embolism.²⁸ In a review of 83 cases of ARDS associated with pregnancy, it was noted that among the causes of ARDS, 35 cases were attributed to uniquely obstetric conditions.²⁹ In addition, it was noted that varicella pneumonia and pyelonephritis were associated with ARDS. These conditions rarely trigger ARDS in immunocompetent adults. De Vaciana et al. pointed out that the development of lung injury in pregnancy correlates with known physiologic changes including increased blood volume, decreased colloid osmotic pressure, and an unchanged critical lung closing volume despite a diminished FRC.³⁰

Management

Management of ARDS includes diagnosis, maternal stabilization, fetal monitoring, investigation and treatment of underlying causes, and in many cases, evaluation for delivery.²⁹

Maternal stabilization includes intubation for mechanical ventilation if necessary. The clinician should consider intubation sooner rather than later in the presence of respiratory deterioration, keeping in mind that a decreased FRC exacerbates respiratory distress.

Contemporary thinking regarding the treatment of ARDS has found that a lung-protective ventilator strategy is the first therapy that has been found to improve outcomes in ARDS. It has been noted in numerous studies that decreasing the V_T from the standard of 12 mL/kg to 6 mL/kg or less and peak inspiratory pressures to less than 30 cm H_2O from 50 cm H_2O have resulted in decreased morbidity and mortality in patients with ARDS.³¹ There has been considerable discussion in the literature concerning permissive hypercapnia and its use in preventing lung injury. However, there have been no controlled studies in pregnancy, and it is the opinion of the author that increasing $Paco_2$ in pregnant patients should be undertaken with caution.

Judicious use of fluids is important in the management of ARDS. Although some authors have advocated the use of fluid restriction, clinicians must consider the volume-dependent status in pregnancy. It is recommended that fluid management be carefully guided by the use of hemodynamic monitoring.

Although oxygenation is important, it should be noted that oxygen should be used at the lowest concentration possible because it is toxic to the lung tissue in high doses. The goal of therapy is to keep the Sao_2 higher than or equal to 95%.

A number of other methods have been discussed in the treatment of ARDS, including inhaled nitric oxide, prostacyclin, surfactant, and inverse ratio ventilation. Currently, these modalities cannot be recommended because they have not been shown to decrease morbidity and mortality. Other trials considering prone ventilation and corticosteroids in late ARDS appear promising but have not been proven in large prospective randomized trials.³²⁻³⁴

Fetal surveillance during ARDS may be more difficult because drugs used to sedate the mother can affect fetal heart rate and variability. Sedatives, anxiolytics, hypnotics, and nondepolarizing agents are not contraindicated in pregnancy. In addition, preterm contractions and labor may present a problem due to maternal hypoxemia. Clinicians are cautioned against starting tocolytic therapy before achieving adequate maternal oxygenation. If tocolysis is needed, β -agonists such as terbutaline should be avoided because of the risk of increased pulmonary capillary permeability and increased demands on cardiac load. Magnesium sulfate is not strictly contraindicated, but it may also increase pulmonary capillary permeability. The use of NSAIDs may be the best choice for tocolysis because they have been proven to improve ARDS in animal models.²⁹ Consultation with a maternal-fetal specialist is recommended to assist intensivists in caring for these complex patients.

The timing of delivery of the patient with ARDS is a question that must be addressed by clinicians. Some authors advocate delivery after maternal stabilization, citing the possible "therapeutic effect" of delivery. Whitty and colleagues failed to demonstrate any significant benefit to delivery.³³ It is this author's opinion that delivery should be considered on a case-by-case basis, carefully weighing the risk/benefit ratio to the mother and fetus.

Box 144-3 shows a reasonable management scheme for a patient with ARDS.

EMBOLISM

Because of the hypercoagulable changes in the coagulation cascade associated with pregnancy, there is an increased risk of venous thromboembolism. It has been estimated that clinically symptomatic pregnancy-related venous thromboembolism occurs in 1 to 2 per 1000 pregnancies. Maternal age (>40 years) and ethnic and genetic

BOX 144-3

Management of the Patient with ARDS

1. Evaluate the patient in respiratory distress; calculate PaO_2/FiO_2 ratio; consider intubation if ≤ 200 mm Hg. The PEEP or CPAP mask is not recommended in pregnancy, owing to the high risk of aspiration.
2. Set tidal volume at 8 to 9 mL/kg to prevent increased peak pressures. Given recent evidence, aim to keep peak pressures less than 40 cm H_2O .
3. Use PEEP starting at 5 to 8 cm H_2O to assist in recruiting alveoli.
4. Aim to keep FiO_2 less than 60%; keep SaO_2 greater than or equal to 95%.
5. Use a pulmonary artery catheter to assist in fluid management and to guide hemodynamic parameters.
6. Consider the use of tocolysis only after the patient has been adequately hydrated and oxygenated.
7. Consider delivery if indicated for obstetric conditions or if continuing the pregnancy has no clear benefit.

ARDS, acute respiratory distress syndrome; CPAP, continuous positive airway pressure; PEEP, positive end-expiratory pressure.

BOX 144-4

Treatment of Pulmonary Embolism in Pregnancy

1. Begin therapy immediately based on strong clinical suspicion while awaiting complete diagnostic workup.
2. Establish the diagnosis with appropriate diagnostic imaging test.
3. Maintain maternal and fetal oxygenation.
4. Administer intravenous heparin and maintain full anticoagulation for 7 to 10 days prior to changing to subcutaneous injections (antepartum) or warfarin (postpartum). Oral anticoagulation should be continued 6 to 8 weeks after delivery.
5. Keep international normalized ratio, activated partial thromboplastin time, or factor Xa level in therapeutic range.

factors may increase this risk. Postpartum thromboembolism is 3 to 5 times more common than antepartum thromboembolic events. A cesarean section confers a risk of 3 to 16 times that of a vaginal delivery.

Clinical signs of a pulmonary embolism include unexplained tachycardia, dyspnea, and diaphoresis and a nonproductive cough. The workup for a suspected pulmonary embolism should include normal laboratory studies (arterial blood gases) and an electrocardiogram in conjunction with radiographic testing.³⁵ Pregnancy should not prevent obtaining appropriate radiographic studies. In patients with a high clinical index of suspicion for thromboembolic phenomena, a definitive diagnosis is imperative (Box 144-4). Ventilation-perfusion scans are recommended as the first diagnostic test. Spiral computed tomography has replaced ventilation-perfusion scanning in many centers as an initial test. Pulmonary angiography is still the gold standard for offering a definitive diagnosis. All of the aforementioned tests use less than the 5 rads of radiation exposure that has been associated with fetal teratogenesis. The use of an abdominal shield further decreases fetal exposure.

D-dimer levels may not be useful for the diagnosis of a thromboembolism during pregnancy because it may be elevated in the absence of a thrombus. Low-molecular-weight heparin (weight-based dosing bid) is the anticoagulant of choice in antepartum patients. Warfarin should be avoided during pregnancy, if possible. Unfractionated heparin can also be used. Neither of these drugs crosses the placenta, owing to the size of the drug molecule. Patients on low-molecular-weight heparin should be monitored with factor Xa levels to ensure a therapeutic level.

Warfarin may be used in the second and third trimesters in patients in whom heparin therapy may be contraindicated. Coumarins may be difficult to reverse and are not routinely recommended during pregnancy. All anticoagulants can be used the postpartum period and are compatible with breastfeeding.³⁶

The goals for therapy during the antepartum and postpartum periods (6-8 weeks post delivery) should be an activated partial thromboplastin time of 2.0 to 2.5, a factor Xa level of 0.6 to 1.1, or an international normalized ratio (INR) of 2.5 to 3.0.

An amniotic fluid embolism is a rare phenomenon that may initially present as severe respiratory distress. Risk factors include rapid labor, multiple gestation, polyhydramnios, and uterine rupture. Patients with an amniotic fluid embolism usually have symptoms of acute respiratory distress, cardiovascular collapse, and profound disseminated intravascular coagulation. Treatment is supportive; however, maternal mortality may be as high as 80%.

■ PNEUMONIA

Concern over the H1N1 virus has reinforced the seriousness of influenza infection in pregnant patients. Historical data have shown that during an influenza pandemic, mortality rates among pregnant women are unusually high. Neuzil et al. noted that even during a normal season, compared to their postpartum counterparts, pregnant women were more likely to be hospitalized.³⁷ The risk of hospitalization was highest in the third trimester, with women nearly five times more likely to be hospitalized than the postpartum control group. Influenza-related morbidity occurs in 10.5 of 10,000 pregnant women, compared to 1.91 of 10,000 in nonpregnant controls. Influenza pneumonia mortality in pregnancy has been noted to range from 12.5% to 42.1%.³⁸

Contemporary management of influenza infection in pregnancy includes the use of antiviral medications for preventing and treating the disease. Amantadine and rimantadine have been shown to be effective in shortening the course and duration of disease in influenza A and influenza B. Recently, oseltamivir (Tamiflu) and zanamivir (Relenza) have been recommended for the prevention of influenza infection. Current Centers for Disease Control and Prevention (CDC) guidelines recommend that treatment be initiated for pregnant women

(including patients until 2 weeks postpartum) with documented exposure to influenza virus and those patients who present with symptoms in the first 48 hours of illness, regardless of their gestational age. Medication should be started at the first sign of symptoms; awaiting confirmation of the diagnosis and delaying therapy could result in rapid progression of the disease. In the 2009 flu season, 6% of deaths were in pregnant women, even though only 1% of the population is pregnant at any given time. Data suggest that the use of antiviral medications significantly reduces perinatal morbidity and mortality. Since 1995, the CDC has recommended that all pregnant women receive influenza immunizations. There has been some discussion regarding the use of thimerosal, which is used in the standard influenza vaccine; most authorities feel that the thimerosal-free vaccine, when available, is preferable. It is the opinion of the author that all pregnant patients who present with respiratory symptoms after exposure to viral illness should be hospitalized for observation.³⁸⁻⁴⁰ Changes in maternal respiratory physiology during pregnancy can make progression from mild respiratory distress to respiratory distress rapid and unpredictable³⁷ (see Fig. 144-1).

■ CONCLUSION

Because of the rare need for mechanical ventilation, there are no randomized controlled trials to determine the treatment modalities that are most effective in pregnancy. A retrospective study noted a maternal mortality rate of 14% and a fetal mortality of 11% in patients who required mechanical ventilation during pregnancy. The critical care specialist, perinatologist, anesthesiologist, and other members of the healthcare team should work closely to provide coordinated care. Understanding the physiologic changes during pregnancy, combined with aggressive treatment of early pathologic changes, will assist in providing improved management in gravid patients with potentially lethal pulmonary complications.

KEY POINTS

Pregnancy

1. Tidal volume is increased during pregnancy; however, functional residual capacity is decreased.
2. A normal arterial blood gas determination in pregnancy reflects compensated respiratory alkalosis.
3. Respiratory distress occurs more rapidly in gravid patients, owing to changes in pulmonary physiology.

Asthma in Pregnancy

1. The treatment of asthma in pregnancy does not differ significantly from that in the nonpregnant state.
2. Because FEV₁ does not change during pregnancy, a peak flow meter is a useful tool in monitoring patients with asthma.
3. A PaCO₂ of greater than 35 mm Hg in the setting of severe asthma represents respiratory distress in the gravid patient.

Acute Respiratory Distress Syndrome in Pregnancy

1. Caution should be used when considering treatment for preterm labor in patients requiring respiratory support. Correction of oxygenation is usually more effective than pharmacologic therapy.
2. The need for mechanical ventilatory support does not mandate delivery of the fetus. Most studies do not report significant maternal improvement after delivery.

3. Sedatives, hypnotic drugs, anxiolytic agents, and nondepolarizing neuromuscular blockade agents are not contraindicated in pregnancy.

Embolism in Pregnancy

1. Pregnancy is a hypercoagulable state that increases the risk of thromboembolic phenomena.
2. Radiographic studies should not be avoided in gravid patients with respiratory compromise.
3. Anticoagulation therapy is not contraindicated in pregnancy; however, warfarin is contraindicated for use in the first trimester.
4. Amniotic fluid embolism occurs in about 1 in 80,000 pregnancies. It is associated with significant maternal morbidity and mortality.

Pneumonia in Pregnancy

1. Pneumonia during pregnancy is the third most common cause of indirect obstetric death.
2. Misdiagnosis may occur in up to 20% of pregnant patients.
3. Care should be taken to carefully evaluate pregnant patients with influenza for acute respiratory symptoms.
4. Prompt pharmacologic treatment for influenza is safe during pregnancy and is recommended by the CDC.

DEFINITION

The commonly accepted definition of *postpartum hemorrhage* (PPH) is excessive and life-threatening bleeding after 20 weeks of gestation, which occurs at the time of delivery of the fetus or placenta. Primary PPH is excessive blood loss within 24 hours of delivery. Secondary PPH is any abnormal or excessive bleeding that occurs between 24 hours and 12 weeks after delivery. Most commonly, bleeding occurs in the third stage of labor, which refers to the time between delivery of the fetus and delivery of the placenta after its separation and expulsion from the uterus. Defining excessive bleeding is somewhat problematic because it can be difficult to determine the exact amount of blood loss, and clinicians tend to underestimate blood loss. With a normal vaginal delivery, blood loss is typically 500 mL or less; after a normal cesarean section, it is usually 800 to 1000 mL. Blood loss greater than these amounts has been used to define PPH. However, uncomplicated vaginal and cesarean deliveries can occasionally occur with greater amounts of blood loss but without hemodynamic compromise. Therefore, a more comprehensive definition of PPH is bleeding (regardless of the volume of shed blood) that is severe enough to cause hemodynamic compromise.

A decrease in hematocrit greater than 10% as a diagnostic criterion has also been widely accepted as a definition of postpartum hemorrhage. The hematocrit level initially may be in the low-normal to normal range despite excessive bleeding, because hematocrit does not change quickly in response to rapid hemorrhage. The hematocrit is also determined in part by the volume of infused resuscitation fluid. Because the parturient's blood volume is increased by 30% to 50%, she may not manifest signs of tachycardia and hypotension until blood loss exceeds 1500 mL. If the patient is hemodynamically unstable but the amount of blood visualized externally is relatively insignificant, occult sites of internal bleeding should be suspected immediately.

INCIDENCE AND MORTALITY

Maternal mortality has significantly decreased over the past 50 years in developed countries, in part because of improvements in obstetric care. However, in the United States maternal mortality rose to a high of 17.8 per 100,000 in 2011. Much of this increase was associated with rising rates of hemorrhage. This increase was the highest among developed countries.¹ Mortality rates are significantly higher for African American and Asian or Pacific Island women compared with Caucasian women.^{2,3} According to a study by the CDC of pregnancy-related mortality in the United States between 2011 and 2012, hemorrhage accounted for 11% of maternal deaths.²

Obstetric hemorrhage is the world's leading cause of maternal mortality, causing 24% of maternal deaths or an estimated 127,000 maternal deaths annually. Postpartum hemorrhage is the most common type of obstetric hemorrhage and accounts for the majority of the 14 million cases of obstetric hemorrhage that occur each year.² In developed countries, PPH may cause up to 40% of all maternal deaths.⁴

PATHOPHYSIOLOGY

At term, blood flow to the uterus and placenta increases to 600 to 1200 mL/min, accounting for 10% of the maternal cardiac output. To

stem the flow of blood and provide immediate hemostasis after delivery of the fetus, the uterus begins to contract. Myometrial contraction is the primary mechanism for both placental separation and hemostasis. The myometrial muscle fibers of the uterus contract and simultaneously retract, causing compression and occlusion of the blood vessels. Uterine atony results when this adaptive mechanism fails and the myometrial fibers are unable to contract and retract normally. Excessive bleeding from the uterus and lower genital tract from many causes, including lacerations, placental anomalies, and trauma, is directly related to the increase in blood flow to the uterus and placenta. At term, there is a physiologic increase in the circulating concentrations of various clotting factors. This adaptive response also helps control the bleeding that is a normal consequence of delivery. However, these factors are overwhelmed by the excessive bleeding of PPH.

PRESENTATION

PPH often manifests as brisk and excessive flow of blood from the vagina. This finding is easily observed on physical examination. If the placenta has been delivered, blood can be seen at the vaginal entrance. Maternal hemodynamics may be unaltered initially. If the bleeding is left untreated, typical presenting signs of hypovolemic shock (i.e., tachycardia, tachypnea, and hypotension) become apparent. Bonnar described the symptoms related to PPH in relation to the amount of blood loss ([Table 145-1](#)).⁵ However, the signs and symptoms of hemorrhagic shock may not occur immediately and may extend over a longer period of time if shed blood is sequestered in the uterus. Occult bleeding occurs most frequently with retained placental fragments, uterine atony, and concealed hematomas in the pelvis, perineum, or retroperitoneal space. Occult hemorrhage in the uterus or hematomas should be suspected in patients who are in the third stage of labor with hemodynamic instability but little or no evidence of external bleeding. Signs and symptoms of excessive bleeding also may be delayed because of the relative hypervolemic state of the patient and by the position of the patient after delivery with the legs elevated in stirrups.

CAUSES

Obtaining a detailed antenatal history is important in helping to determine a possible cause of PPH. A history of prior bleeding episodes associated with heavy menses or with dental or surgical procedures should raise the possibility of an underlying coagulation or bleeding disorder. Significant predisposing risk factors for the development of PPH include previous episodes of PPH, multiparity, and multiple fetuses. Women with a prior history of PPH can have up to a 15% risk of recurrence with subsequent pregnancies.⁶ Risk factors associated with the development of PPH are listed in [Box 145-1](#). Early recognition of these risk factors may aid in the diagnosis and subsequently in the management of PPH. A randomized, controlled trial (RCT) comparing oxytocin administration before and after delivery of the placenta found that birth weight, labor induction with augmentation, chorioamnionitis, use of magnesium sulfate infusions, and previous episodes of PPH increased the risk of developing PPH.⁷ However, a significant number of patients with PPH have no obvious predisposing factors.

Potential causes of PPH are listed in [Box 145-2](#). Risk factors for obstetric causes at the time of admission should be identified and

TABLE 145-1 Presentation of Symptoms in Postpartum Hemorrhage

| % BLOOD LOSS (mL) | SYSTOLIC BLOOD PRESSURE (mm Hg) | SIGNS AND SYMPTOMS |
|------------------------------------|---------------------------------|--------------------------------------|
| Stage I 10-15 (500-1000) | Normal | Tachycardia, palpitations, dizziness |
| Stage II 15-25 (1000-1500) | Low-normal | Tachycardia, weakness, diaphoresis |
| Stage III 25-35 (1500-2000) | 70-80 | Restlessness, pallor, oliguria |
| Stage IV 35-45 (2000-3000) | 50-70 | Collapse, air hunger, anuria |

BOX 145-1 Predisposing Risk Factors for Obstetric Hemorrhage**LOW RISK**

No previous uterine incision
 Singleton pregnancy
 <4 previous vaginal births
 No known bleeding disorder
 No history of PPH

MODERATE RISK

Prior cesarean section or uterine surgery
 Multiple gestation
 >4 previous vaginal births
 Chorioamnionitis
 History of previous PPH
 Polyhydramnios
 Large uterine fibroids

HIGH RISK

Placenta previa or low lying
 Suspected accreta or percreta
 HCT < 30 AND other risk factors
 Platelets < 100,000
 Active bleeding on admission
 Known coagulopathy

PPH, postpartum hemorrhage.

BOX 145-2 Causes of Postpartum Hemorrhage

Uterine atony
 Cervical or vaginal lacerations
 Retention of placental fragments
 Placental anomalies
 Traumatic hematomas of the perineum or pelvis
 Coagulation disorders
 Uterine rupture
 Uterine inversion

reassessed during the intrapartum and postpartum process. The most frequent cause of PPH is uterine atony after delivery of either the fetus or placenta. Bleeding is from the uterine vessels or from the placental site of implantation if the placenta has been delivered. The incidence of uterine atony is approximately 1 in 20 deliveries. Uterine atony can lead to rapid and severe PPH. Overdistention of the uterus secondary to multiple gestation, fetal macrosomia, or polyhydramnios is a major predisposing risk factor for the development of uterine atony. Other predisposing factors are retained placenta, chorioamnionitis, uterine structural abnormalities, and muscle fatigue after prolonged or stimu-

lated labor. General anesthesia, particularly with halogenated anesthetics, and magnesium sulfate infusions can inhibit effective uterine contractions and lead to uterine atony. The diagnosis of uterine atony is a clinical diagnosis made by assessing the tone of the uterus and its size by manually palpating the uterus externally. Bimanual examination of the uterus also can be performed to diagnose uterine atony. A boggy uterus associated with heavy vaginal bleeding or with an appreciable increase in the size of the uterus is diagnostic of uterine atony. The size of the uterus may be larger than normal due to accumulated blood within.

Lacerations of the lower genital tract are the second most frequent cause of PPH. Lacerations of the vagina and cervix can result from a number of causes. These lesions occur most commonly as a result of prolonged or tumultuous labor, particularly with uterine hyperstimulation with oxytocic agents. Nevertheless, lacerations can occur spontaneously as well. They are seen in deliveries associated with instrumentation, such as forceps deliveries, or with extrauterine or intrauterine manipulations of the fetus. Attempts to remove the placenta or placental fragments manually or with instrumentation can lead to traumatic lesions or hematomas. Excessive vaginal bleeding or traumatic hematomas can result from these lacerations. Careful examination with palpation of the vagina and cervix may reveal the presence of lacerations.

Retention of placental fragments or the entire placenta can lead to severe and life-threatening hemorrhage, which may be immediate or delayed depending on the extent of accumulated blood in the uterus. The most common definition of retention of the placenta in utero is when part or all of the placenta is retained in the uterus for more than 30 to 60 minutes after delivery of the fetus. Retained placenta is more likely to occur with a preterm gestation of less than 24 weeks.

Placental abnormalities (i.e., placenta accreta, placenta increta, and placenta percreta) have been associated with retained placenta and failure of complete separation of the placenta from the uterus. If the placenta has been delivered, it is imperative to closely examine the placenta to look for missing fragments, a finding that suggests retained placental tissue.

Placenta accreta occurs when a portion or the entire surface of the placenta is abnormally attached to the uterus. Where placenta accreta is present, the failure of the placenta to separate normally from the uterus after delivery is accompanied by severe postpartum hemorrhage. Placenta increta involves actual invasion of the uterus by the placenta. Placenta percreta involves invasion of the placenta into other organs. Multiple uterine surgeries, such as cesarean sections, or other uterine procedures like uterine ablation increase the risk of placental invasion. If placental invasion is anticipated, the patient should be delivered in a center with experience in taking care of these patients.

Another less frequent cause of PPH is uterine rupture. Rupture is more common in patients with prior cesarean incisions and in those with any prior operative procedures of the uterus (e.g., intrauterine device placement, laparoscopy, hysteroscopy). Uterine rupture may manifest with severe and acute abdominal pain and hemodynamic instability, but there may not be significant bleeding initially. Uterine inversion is relatively uncommon but may be associated with blood losses of up to 2 L.

A defect in hemostasis resulting from an underlying coagulopathy should be considered if the uterus is contracting normally and manual exploration has excluded either placental retention or uterine rupture. Disseminated intravascular coagulation (DIC) associated with placental abruption (premature separation of a normally implanted placenta), the HELLP syndrome (*hemolysis, elevated liver enzymes, and low platelets*), intrauterine fetal death, acute fatty liver of pregnancy, sepsis, or amniotic fluid embolism may precipitate PPH. The incidence of severe DIC associated with PPH is estimated at 0.1% of pregnancies.⁸

Amniotic fluid embolism syndrome (AFES) is a catastrophic condition that can occur either during the pregnancy or after the delivery. AFES manifests with acute respiratory failure, cardiogenic shock, and/or DIC.⁹ As many as 80% of these patients develop DIC, and in some, DIC is the major clinical abnormality. Oozing from intravenous (IV)

or skin puncture sites, mucosal surfaces, or surgical sites should raise the suspicion of DIC; confirmation of the diagnosis is made by laboratory coagulation studies. Although the coagulation profile is unlikely to be abnormal with acute postpartum bleeding in the absence of DIC, coagulation parameters are clearly abnormal in the presence of DIC regardless of the cause. In late pregnancy, the circulating fibrinogen level usually is two to three times the normal prenatal value, but fibrinogen concentration is dramatically decreased if DIC is present. Preexisting or pregnancy-acquired disorders of coagulation are relatively infrequent causes of significant PPH.

DIAGNOSTIC STUDIES

Although the diagnosis is obvious with significant and excessive bleeding after delivery, not all patients present with immediate bleeding, because of hematoma formation or accumulations in the interior of the uterus. Bedside ultrasonography can be used for the detection of clots, hematomas, and retained placental products. For patients who are at high risk for development of PPH, periodic ultrasound examinations during pregnancy can offer invaluable information concerning the extent and progression of placental disease. Angiography with selective arterial embolization can be used both diagnostically and therapeutically. Bleeding sites can be visualized and embolized simultaneously. For evaluation of a proven or suspected case of PPH, the following laboratory studies are almost always indicated: complete blood count with platelet count, coagulation studies with prothrombin and activated partial thromboplastin times, fibrinogen, and fibrin split products. D-dimer may be a limited use as it may be elevated in normal pregnancies. With acute hemorrhage, the measurements of hemoglobin concentration and hematocrit may be of limited use.

PREVENTION

There has been much controversy concerning the preferred methods of managing the third stage of labor in terms of decreasing bleeding complications. The debate concerns active versus expectant management. Expectant management consists of waiting for separation and expulsion of the placenta, with minimal intervention except for gentle fundal massage. Active management of the third stage of labor involves three components. The first consists of administering a uterotonic drug, usually oxytocin, immediately after delivery of the fetus to promote contraction of the uterus and subsequent expulsion of the placenta. The second maneuver consists of gentle traction on the umbilical cord after the uterus is well contracted and then using countertraction against the uterine fundus.¹⁰ The third maneuver is uterine massage after delivery of the placenta. The two modalities were compared in five randomized, controlled trials in a Cochrane meta-analysis of studies enrolling more than 6000 women. A 60% decrease in PPH was associated with active management of the third stage of labor.¹¹

GENERAL TREATMENT MEASURES

Many deaths associated with PPH may have resulted because clinicians underestimated the extent of blood loss and failed to provide rapid and aggressive resuscitation with fluids and blood products. Several authors have suggested the use of specific management protocols for the care of patients with PPH.^{5,12,13} These guidelines can expedite rapid diagnosis and management of obstetric hemorrhage. Quantification of blood loss during delivery has been recommended as it gives a better assessment of blood loss. Several current toolkits are available to assist medical personnel in managing the weighing of pads and laps in order to give an accurate assessment. Simulation may also be used to assist the team in responding more quickly to this emergency.

A general assessment of the patient, evaluation of vital signs, a detailed physical examination, and a review of the obstetric delivery details are all necessary for the clinician to formulate a comprehensive evaluation and critique of the situation. The general treatment mea-

BOX 145-3

General Treatment Measures for Postpartum Hemorrhage

Oxygen administration
Gentle massage of the uterine fundus
Placement of large-caliber intravenous catheters for rapid and aggressive fluid resuscitation with isotonic solutions using the "3:1" rule
Blood product administration depending on the extent of bleeding and coagulation abnormalities

TABLE 145-2

Therapeutic Response to Initial Fluid Resuscitation

| RESPONSE | DESCRIPTION | FOLLOW-UP TREATMENT |
|------------------------|---|---|
| Rapid response | <20% of blood volume lost | No additional fluids or blood are needed. |
| Transient response | 20%-40% of blood volume lost; responds to initial fluid bolus but later has worsening vital signs | Continue fluids and consider blood transfusions. |
| Minimal or no response | Ongoing severe hemorrhage with >40% blood volume lost | Continue aggressive fluid and blood product replacements. |

asures for PPH are the same as those for any patient with acute hemorrhage (Box 145-3). Oxygen should be administered routinely. At least two large-caliber IV lines should be placed immediately. Central venous access is usually unnecessary unless peripheral access cannot be obtained quickly. Aggressive volume resuscitation should be instituted immediately, because this intervention can be lifesaving in patients with ongoing bleeding and hemodynamic instability. Either normal saline or lactated Ringer's solution is the preferred fluid for aggressive resuscitation. Isotonic electrolyte solutions provide transient intravascular volume expansion. Monitoring of changes in blood pressure, heart rate, and pulse pressure can help the clinician to determine the amount of blood loss, particularly in cases in which bleeding is internal (Table 145-2).

General guidelines for fluid resuscitation of patients with hemorrhagic shock are based on the "3:1" rule. This recommendation derives from the empiric observation that patients require about 300 mL of crystalloid fluid replacement for every 100 mL of blood loss. This rule must be applied in the context of the clinical scenario. Applied blindly, this guideline can result in either excessive or inadequate volume resuscitation. Patients with expanding hematomas or areas of concealed active bleeding have hypotension out of proportion to the obvious blood loss and require resuscitation in excess of the 3:1 recommendation. In contrast, patients with ongoing blood losses that are being replaced with blood transfusions typically require less electrolyte fluid replacement. Although initial fluid resuscitation is critical, caution should be exercised to prevent abdominal compartment syndrome that may occur when more than 10 L of fluids are administered. Red blood cell transfusions to replace ongoing blood loss remain the mainstay of fluid replacement.

Blood transfusions usually are necessary for patients with severe ongoing PPH. Healthy pregnant patients usually do not require transfusion if blood loss is 2000 mL or less. However, if blood loss is greater than 2 L or there is ongoing hemorrhage and hemodynamic instability, transfusion can be lifesaving. Crossmatched packed red blood cells or type-specific blood can be infused rapidly using a blood-warming device in cases of severe ongoing hemorrhage (Box 145-4). Recombinant activated factor VII (rFVIIa) has been recommended in cases of refractory postpartum hemorrhage that has not responded to medical

BOX 145-4 Blood Product Replacement

Crossmatched blood
 Type-specific or "saline crossmatched" blood
 Compatible ABO and Rh blood types
 Rh-negative blood is preferable.
 Warm the blood, if possible, especially if the rate of infusion is >100 mL/min or if the total volume transfused is high; cold blood is associated with an increased incidence of arrhythmias and paradoxical hypotension.
 Administer calcium if blood is transfused rapidly at >100 mL/min because of binding of calcium by anticoagulants in banked blood.
 Give 6-10 units fresh frozen plasma (FFP) for every 10 units of packed red blood cell (PRBC) transfusions.
 Give 10-12 units of platelets if the platelet count decreases to $<50 \times 10^9$ /L.
 Cryoprecipitate can be given to replace fibrinogen in addition to the FFP.
 Consider 60-120 μ g/kg intravenous bolus injection of recombinant activated factor VII (rFVIIa).

measures including blood product administration.¹⁴ Although supported by few and uncontrolled studies, the available data suggest a potential role of rFVIIa in the management of severe PPH prior to performing a definitive hysterectomy.

Manual external uterine massage should be performed immediately to stimulate uterine contractions and express clots if uterine atony is suspected or confirmed. If the uterus does not respond to vigorous manual external massage and the rapid administration of oxytocin, bimanual massage with one hand on the uterus and the other hand placed anterior to the cervix in the vagina should be performed. Aggressive uterine manipulation can result in uterine inversion. Direct pressure should be maintained over visible perineal, vaginal, or cervical lacerations. These general treatment measures can control excessive bleeding and even stop the hemorrhage in a significant proportion of patients.

SPECIFIC TREATMENT MEASURES

Oxytocic (uterotonic) drugs administered IV, intramuscularly, or intramyometrially are used to stimulate the uterus by producing rhythmic contractions and control the degree of hemorrhage. Dosing regimens for oxytocic drugs are listed in Table 145-3.

Oxytocin (Pitocin) remains first-line therapy for most obstetricians. Prophylactic oxytocin, given either before or after placental delivery, decreases the incidence of PPH up to 40%.¹⁵ It is also used prophylactically after delivery of the fetus but before delivery of the placenta to decrease the duration of the third stage of labor and the amount of blood loss. In an RCT, the incidence of PPH was similar regardless of whether oxytocin was given before or after placental delivery.⁷ Additionally, the incidence of retained placenta was similar for patients treated with oxytocin before or after delivery of the placenta. Oxytocin should be used with caution in patients with hyperactive uterine contractions or hypertension, because the pressor effect of sympathomimetic drugs can increase if they are used with oxytocin.

Methylergonovine (Methergine) is now considered second-line therapy. It is a direct uterotonic agent that reduces uterine bleeding and shortens the third stage of labor. Hypertension is a relative contraindication for the use of Methergine. Carboprost tromethamine (Hemabate), a synthetic prostaglandin similar to prostaglandin $F_{2\alpha}$ but with a longer duration, produces myometrial contractions that induce hemostasis at the placentation site, reducing postpartum bleeding. It is used in some centers as a second-line uterotonic agent. Asthma is a relative contraindication to the use of carboprost. Carboprost has been shown to be as effective in decreasing PPH refractory to oxytocin and ergonovine. Misoprostol, prostaglandin E_1 , causes uterine contractions, and rectal administration of this drug has been shown to be useful in refractory PPH. Although oxytocin is considered the standard of care for treating postpartum hemorrhage, it is not always viable or available, particularly in resource-poor clinical settings, because of

TABLE 145-3**Dosing Regimens for Oxytocic Drugs**

| DRUGS | REGIMENS |
|--------------------------------|---|
| Oxytocin (Pitocin) | 5-unit IV bolus Add 20-40 units oxytocin to 1 L of fluids. 10 units intramyometrially |
| Methylergonovine (Methergine) | 0.2 mg IM every 2-4 h |
| Ergonovine maleate (Ergotrate) | 100-125 μ g IM or intramyometrially every 2-4 h 200-250 μ g IM Total dose 1.25 mg |
| Carboprost (Hemabate) | 250 μ g IM or intramyometrially every 15-90 min Total dose 2 mg |
| Misoprostol | 800 μ g PR or 800 μ g of sublingual misoprostol |

IM, intramuscular; IV, intravenous; PR, per rectum.

refrigeration requirements and the need for IV administration. In a large randomized prospective trial, the efficacy and acceptability of 800 μ g of sublingual misoprostol were compared to 40 international units of IV oxytocin to control postpartum bleeding.¹⁶ The primary endpoints were cessation of active bleeding within 20 minutes and additional blood loss of 300 mL or more after treatment. The findings suggested that sublingual misoprostol is a viable alternative to 40 international units of IV oxytocin for treatment of primary postpartum hemorrhage after oxytocin prophylaxis during the third stage of labor. Misoprostol stopped bleeding as rapidly as oxytocin and with a similar quantity of additional blood loss.

The practice of uterine packing to control bleeding remains somewhat controversial. Although this practice had been abandoned for many years, it has recently resurged as an effective method for tamponade of bleeding from the uterus. Balloon occlusion catheters have been used in the treatment of PPH.¹⁷ Recent data suggest that balloon tamponade is an effective method for controlling hemorrhage, and in 80% of cases hysterectomy was averted. When a specific uterine balloon catheter is not available, placement of a Sengstaken-Blakemore tube or a large Foley catheter can also be used for control of bleeding.¹⁸

If there is a suspicion of retained placenta, examination of the uterus is both diagnostic and therapeutic. The uterus must be explored digitally and retained placental fragments removed either manually or with instruments. Because this procedure can be difficult and quite painful, it may be necessary to use regional or general anesthesia to obtain optimal visualization and manipulation of the uterus. Administration of oxytocic drugs should continue during manual extraction of placental fragments. Administration of broad-spectrum antibiotics has been recommended whenever there is manipulation or instrumentation of the uterus.

Compression of the abdominal aorta against the vertebral column, which can be achieved by pressing a fist on the abdomen cephalad to the umbilicus, can be a lifesaving temporizing maneuver to control hemorrhage before surgery in the presence of fulminant bleeding with severe hemodynamic compromise. If there is persistent and significant bleeding despite the therapeutic measures described, consideration should be given to arteriography with selective arterial embolization. This procedure requires the expertise of an interventional radiologist and may not be readily available in many hospitals. Successful embolization of the bleeding sites can be accomplished, obviating the need for surgical intervention.¹⁹ Fertility can be preserved with this procedure.²⁰ Prophylactic placement of embolization catheters in patients at high risk for PPH to minimize the procedural delay in the presence of active bleeding has also been utilized in some centers. If embolization is unsuccessful, balloon catheter occlusion of the hypogastric and iliac arteries has been successfully performed as a temporizing measure

before surgery.²¹⁻²³ Complications are minimal, and postprocedural fever appears to be the most common complication of the procedure.

SURGICAL THERAPY

Surgical therapy is reserved for cases not amenable to medical therapy. Patients with ongoing hemorrhage despite aggressive medical therapy are candidates for operation. Surgery is the treatment of choice for uterine rupture. Lacerations, if visible, are directly repaired and oversewn. Lacerations high in the vaginal vault or in the cervix may require operative repair, primarily for improved visualization of the lesions. Hematomas of the lower genital tract are incised and drained. Arterial embolization of vaginal and vulvar lesions has been used. Hematomas of the broad ligament and in the retroperitoneal space are often managed conservatively if there is only minimal further expansion of the hematoma, but surgical exploration or embolization is mandated if additional significant bleeding occurs. Radiographic imaging with computed tomography, magnetic resonance imaging, and/or ultrasonography is a useful adjunct to monitor the expansion of these hematomas.

Ligation of the uterine, ovarian, or internal iliac (hypogastric) arteries can be performed. The uterine arteries provide 90% of uterine blood flow. Ligation of these arteries can often control bleeding with success rates of up to 92% and a complication rate of 1%.²⁴ If hemostasis is not achieved with uterine artery ligation, the ovarian and internal iliac arteries can be ligated as well. Ligation of the internal iliac arteries is technically more difficult, and success rates range from 40% to 100%.^{24,25} Ligation of the internal iliac arteries usually is done only if ligation of the uterine and ovarian arteries has proved unsuccessful in halting bleeding.

Uterine compression sutures running through the full thickness of both uterine walls (posterior as well as anterior) have recently been described for surgical management of atonic PPH.²⁶⁻²⁸ The different uterine suture techniques have proved to be valuable and safe alternatives to hysterectomy in the control of massive PPH. In contrast, hys-

terectomy remains the definitive surgical therapy to control bleeding. Hysterectomy is required if bleeding continues despite ligation of the internal iliac arteries. Subtotal or total hysterectomy is curative in PPH. In cases of uterine rupture, it is the only surgical option, and nonsurgical modalities are only temporizing measures until the patient can be brought to the operating room. In developed countries, the incidence of postpartum emergent hysterectomy is approximately 1 in 2000 deliveries. Rossi et al. reviewed 24 articles that included 981 cases of emergency postpartum hysterectomy. They found women at highest risk of emergency hysterectomy are those who are multiparous, had a cesarean delivery in either a previous or the present pregnancy, or had abnormal placentation.²⁹

COMPLICATIONS

Serious morbidity may follow PPH. Complications from postpartum bleeding include hematologic abnormalities such as DIC and dilutional coagulopathy from massive fluid resuscitation and/or massive transfusion (greater than 10 units of packed red blood cells). New protocols suggest that aggressive transfusion with whole blood or packed red blood cells and fresh frozen plasma in a 1:1 ratio may reduce the incidence of DIC in this population.³⁰ Dilutional coagulopathy occurs when more than 80% of the original blood volume has been replaced. Life-threatening complications of hemorrhagic shock, including renal failure and liver failure, acute respiratory distress syndrome (ARDS), and pituitary necrosis (Sheehan's syndrome), can occur. Sheehan's syndrome can result from severe PPH that causes permanent hypopituitarism from avascular necrosis of the pituitary gland.³¹

PROGNOSIS

The prognosis of PPH depends on many factors, some of which are directly related to prompt diagnosis and treatment. The cause of bleeding, the duration of bleeding, and the extent of bleeding all affect the likelihood of a good outcome.

KEY POINTS

1. *Postpartum hemorrhage* (PPH) is defined as excessive bleeding after a vaginal or cesarean delivery that can be associated with hemodynamic instability if the bleeding is severe.
2. The usual signs of tachycardia and hypotension associated with severe bleeding may not manifest early because of the relative hypervolemic state of pregnancy or in cases of concealed hematomas with ongoing blood losses.
3. PPH is the leading cause of maternal death worldwide and one of the major causes of death in the United States, along with embolism, infection, and hypertensive disorders of pregnancy.
4. Massive blood loss can occur from the uterus because of the significant physiologic increase in blood flow to the uterus at term.
5. Occult bleeding occurs most frequently with retained placental fragments, uterine atony, and concealed hematomas in the pelvis, perineum, or retroperitoneal space.
6. Women with a prior history of PPH have a 10% risk of recurrence with a subsequent pregnancy.
7. Many women have predisposing factors leading to the development of PPH. Antenatal identification of potential predisposing factors allows for close monitoring of the high-risk patient.

Women with multiple cesarean sections may pose one of the highest risks for hemorrhage.

8. The most frequent cause of PPH is uterine atony, which occurs in 1 of every 20 deliveries. Risk factors for uterine atony include overdistention of the uterus, retained placenta, uterine muscle fatigue, and use of halogenated anesthetic agents.
9. The diagnosis of uterine atony is made clinically by palpation of a boggy and enlarged uterus.
10. The second most frequent cause of PPH is lacerations of the lower genital tract that occur as a result of traumatic labor or spontaneously.
11. Manual exploration of the uterus confirms the diagnosis of retained placental fragments. Placental retention is most commonly associated with several types of placental anomalies.
12. Disseminated intravascular coagulation (DIC) is associated with placental abruption, the HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets), acute fatty liver of pregnancy, intrauterine fetal death, sepsis, and amniotic fluid embolism.
13. Amniotic fluid embolism syndrome usually manifests as sudden and acute respiratory failure, cardiogenic shock, and DIC.
14. In the United States, most obstetricians practice expectant management of the third stage of labor, allowing for spontaneous

KEY POINTS—cont'd

- delivery of the placenta. Active management of the third stage of labor involves fundal massage, use of an oxytocic drug, and gentle traction on the umbilical cord, with countertraction of the uterus to facilitate delivery of the placenta.
15. General treatment measures include aggressive and early fluid resuscitation while investigating the potential source of the bleeding. Higher maternal mortality rates are seen when blood losses are underestimated and treatment is delayed.
 16. Patients with ongoing severe bleeding, blood losses greater than 2 L, or hemodynamic compromise require blood transfusions in addition to volume resuscitation.
 17. Specific treatment modalities include administration of oxytocic drugs, uterine packing, tamponade procedures with arterial balloon occlusion, and selective arterial embolization.
 18. Surgical therapy is reserved for cases of uterine atony and after all other modalities have failed. Uterine, ovarian, and iliac artery ligations and uterine compression sutures have been successful in controlling bleeding.
 19. Total or partial hysterectomy is the definitive surgical procedure. Uterine rupture necessitates a hysterectomy.
 20. Complications from PPH are the same as those of hemorrhagic shock, with risk of multiple organ failure, acute respiratory distress syndrome, dilutional coagulopathy, and Sheehan's syndrome.
 21. Sheehan's syndrome results from severe PPH and manifests as severe hypopituitarism.
 22. The prognosis of PPH depends on the cause of the bleeding, its extent and duration, and the speed of diagnosis and treatment.

- The ACOG (American College of Obstetricians and Gynecologists) Practice Bulletins provide obstetricians and gynecologists with current information on established diagnostic techniques and clinical management guidelines for a wide variety of clinical scenarios and various disease processes, including review of the etiology, evaluation, and management of postpartum hemorrhage.
- Creanga AA, Berg CJ, Syverson C, Seed K, Bruce FC, Callaghan WM. Pregnancy-related mortality in the United States, 2006–2010. *Obstet Gynecol* 2015;125:1.
- The objective of this epidemiologic study, using data from the Pregnancy-Related Mortality Surveillance System of the CDC, was to examine the trends of risk factors and causes for maternal mortality and to identify patients at high risk for death. Since 1979, the CDC and ACOG have collected information on all maternal deaths in the United States. Results showed that maternal death rates, which had been decreasing annually after 1979, began to increase from 1987, with a peak in 2010. The three leading causes of maternal death were hemorrhage, embolism, and hypertensive disorders of pregnancy. The number of deaths due to hemorrhage and anesthesia complications has decreased, but deaths associated with heart disease and infection have increased.

Developed under contract #11-10006 with the California Department of Public Health; Maternal, Child and Adolescent Health Division. Published by the California Maternal Quality Care Collaborative, 3/17/15.
- The objective of this toolkit is to provide programs with a collaborative approach to managing postpartum hemorrhage. Many of the components of the tool kit are part of the National Safety Bundle. The goals are to allow for readiness for every patient, recognition for every patient, and response for every unit. Emphasis is placed on preventing hemorrhage by actively managing the third stage of labor. Studies have demonstrated that following protocols and quality improvement have led to a decrease in maternal morbidity and mortality.
- Jackson KW Jr, Allbert JR, Schemmer GK, et al. A randomized controlled trial comparing oxytocin administration before and after placental delivery in the prevention of postpartum hemorrhage. *Am J Obstet Gynecol* 2001;185:873.
- The objective of this RCT was to determine the optimal time to administer oxytocin in the third stage of labor. Previous studies had shown a decreased incidence of PPH when prophylactic oxytocin was given after fetal or placental delivery. However, opponents of this practice are concerned about the potential risk of retained placental parts. In this study, 1486 patients were randomly assigned to receive oxytocin either at presentation of the fetal anterior shoulder or with delivery of the placenta. The authors found no difference in frequency of PPH or in duration of the third stage of labor when oxytocin was given before or after delivery of the placenta. There was no increase in the incidence of retained placenta among those patients who received oxytocin after delivery of the fetus but before delivery of the placenta. Their final recommendation was to proceed with active management of the third stage of labor with controlled cord traction until the placenta is removed. Oxytocin can be given either before or after placental delivery to facilitate uterine contractions.
- Rossi AC, Lee RH, Chmait RH. Emergency postpartum hysterectomy for uncontrolled postpartum bleeding: a systematic review. *Obstet Gynecol* 2010;115:637.
- The objective of this review was to describe factors leading to and outcomes after emergency postpartum hysterectomy for uncontrolled postpartum hemorrhage. PubMed, MEDLINE, EMBASE, and Cochrane Library databases were used for the search up to August 2009. Twenty-four articles that included 981 cases of emergency postpartum hysterectomy were reviewed. Their findings showed that women at highest risk of emergency hysterectomy are those who are multiparous, had a cesarean delivery in either a previous or the present pregnancy, or had abnormal placentation.

One of the most challenging critical care situations is the care of a pregnant patient who develops critical illness.¹ The complexity of care is increased by constraints imposed by concerns for balancing maternal health with the health of the unborn or, in some cases, recently born child. Although many potential critical illnesses may occur during pregnancy, we focus our discussion on neurocritical illness that may arise, leading to an intensive care admission in this chapter. We further focus on the ongoing developments in this topical area and on the critical care aspects of care, most typical of late-term pregnancy.

The main points to emphasize in this chapter are as follows: (1) Pregnancy creates a condition prone to inflammatory and thrombotic disease in the brain.^{1,2} (2) Treatments of common conditions, such as seizures, are unique in a pregnant woman. (3) Systemic circulatory concerns need to be adjusted for consideration of intracranial hemodynamics. (4) Brain monitoring may be useful to guide therapy and limit toxicity of treatments.

There are three main diagnoses or conditions that complicate pregnancy and lead to neurologic emergencies. These are myasthenic crisis, preeclampsia/eclampsia with seizures, and ischemic or hemorrhagic stroke. We explore the important critical care bedside considerations and treatment approaches to each of these conditions and focus on decision making and integration with general critical care goals.

FUNDAMENTAL PEARLS FOR NEUROCRITICAL CARE

As we begin our discussion, it is important to follow certain fundamentals of neurocritical care in assessing a pregnant patient who presents with neurologic deterioration. The important steps are as follows: (1) Obtain a detailed history of the timing and specifics of the neurologic deterioration. This is in contrast to our routine practice in critical care of assessing a brief synopsis of the presentation. A detailed approach will help discriminate between central and peripheral nervous system diseases, the presence of symptoms of elevated intracranial pressure, seizures, and similar pathophysiology. (2) Perform a detailed neurologic examination that can be compared to future examinations. This is important to assess the clinical treatment and also important to avoid misdiagnosing a peripheral neurologic problem as being a central nervous system problem, and vice versa. (3) Closely evaluate brain imaging for signs of intracranial hypertension. For most pregnant patients, the risks of computerized tomography (CT) are acceptably low so that a brain CT can be obtained. Magnetic resonance imaging (MRI, including MR venography) may be preferred but may not be feasible in critically ill patients. (4) Make use of brain monitoring for seizures in obtunded or encephalopathic pregnant patients. This may include transcranial Doppler ultrasound (TCD) and electroencephalography. As you will read later, seizures are a major problem for pregnant patients. (5) Develop an approach to optimize the intracranial hemodynamics in patients suspected of intracranial hypertension or cerebral ischemia. This may result in blood pressure (BP), mechanical ventilation, or systemic hemodynamic management that is considerably different from what would be optimal for an uncomplicated pregnancy. (6) Discuss fetal-maternal balance issues with an obstetrician, and seek treatment parameters that favor the welfare of the mother without harming the fetus if possible.

MYASTHENIC CRISIS

Myasthenia gravis (MG) during pregnancy usually does not result in critical illness.³ There is a large fraction of patients who will have improvement in MG during pregnancy. For general myasthenic care, consultation with a neurologist should be done, as standard treatments such as steroids may entail an increased risk of birth defects (e.g., cleft palate). For the most part, the routine care of MG will not change during pregnancy, and the typical medications may be used. For the 30% of patients who demonstrate myasthenic crisis, some are in the postpartum period.³ The main clinical questions concern the optimal critical care for pregnant patients with myasthenic crisis and the optimal disease-modifying treatment while in crisis in the intensive care unit (ICU).

Myasthenic crisis can be complicated by acute respiratory failure due to diaphragm fatigability. In the ICU, the clinical examination of facial and eyelid weakness, bulbar weakness, tachypnea with paradoxical respirations, and limb weakness are helpful diagnostic clinical signs of myasthenic crisis. Monitoring of vital capacity and negative inspiratory force is desirable as additional diagnostics. The respiratory mechanics, criteria for intubation, and methods of mechanical ventilation are similar to those of nonpregnant patients. Definitive treatment with the use of plasmapheresis or intravenous (IV) immunoglobulins is considered to be safe and effective for myasthenic crisis during pregnancy. The standard doses and scheduling apply. However, a few special considerations of plasmapheresis during pregnancy include an increased risk of perinatal bleeding because of depletion of coagulation factors.^{3,4} It is recommended that plasmapheresis be withheld 24 hours before childbirth.⁴ The newborn must be monitored for hypogammaglobulinemia and perinatal infections. Positioning of the mother on her left side during apheresis is a specific precaution to avoid compression of the vena cava. Monitoring of circulating blood volume and avoidance of hypovolemia are other unique precautions.

Post birth, about 10% of newborns develop neonatal MG because of the transfer of maternal antiacetylcholine receptor antibodies. This is usually short-lived but requires supportive care for a short duration, usually 12 to 24 hours.

PREECLAMPSIA AND ECLAMPSIA

Preeclampsia/eclampsia (PE/EC) is a mid- to late pregnancy clinical problem that initially manifests as new hypertension in pregnancy.⁵ The underlying pathophysiology may be related to increased cerebral blood flow and loss of cerebral autoregulation.^{6,7} The threshold for systolic BP is more than 140 with repeated elevations over time. The systemic hypertension may be accompanied by other systemic problems including proteinuria, acute kidney injury, acute liver transaminase elevation, or combinations of these findings.⁵ Alteration of mental status may occur as well as mild confusion or visual symptoms. Seizures are typically later stage manifestation, and once seizures occur, the patient is considered eclamptic. The timing of this problem is typically before birth but may occur during delivery or 1 to 4 weeks after childbirth. The highest risk period is during labor.^{5,8} The seizures are most commonly generalized tonic-clonic seizures but may be focal with altered mental status. The seizures may take the form of status epilepticus (SE) and be severe enough to induce coma.

TABLE 146-1 Drugs for PE/EC in a Pregnant Woman

| TRIGGER | DRUG | DOSE | MONITOR |
|---------------------|-------------------|---------------|--------------------------|
| SBP >140 | Magnesium | 4-6 g IV push | BP |
| SBP >140 | Magnesium | 1-3 g/h IV | BP, reflexes, dysarthria |
| Refractory SBP >140 | Hydralazine | 5-10 mg IV | BP response |
| Seizure | Magnesium | 1-3 g/h IV | Clinical or EEG |
| Seizure | Anticonvulsant IV | Loading dose | EEG |

BP, Blood pressure; EEG, electroencephalography; PE/EC, preeclampsia/eclampsia; SBP, systolic blood pressure.

The critical care for the preeclamptic/eclamptic (PE/EC) woman is focused on early reduction in BP and prevention of seizures. In contrast to the standard use of antiseizure medications, the use of intravenous magnesium is the mainstay of treatment.⁸ Table 146-1 outlines the treatment approach in PE/EC.

The patient with PE/EC is typically monitored for changes in BP with the goals of the normal range of BP (130-150/90-100). Hydralazine and labetalol have each been demonstrated to be useful in controlling BP in PE/EC. During the control of BP, cerebral perfusion pressure (CPP) should also be considered. As a reminder, CPP is the mean arterial pressure (MAP) – intracranial pressure (ICP), or CPP = MAP – ICP. The lower limit of the normal CPP is usually 60 mm Hg. In most situations, the ICP is unknown in a PE/EC woman, but this is where the brain imaging can be helpful. If the brain appears normal on CT, the ICP can be considered to be 10 mm Hg, and hence the MAP would need to be more than 70 mm Hg to provide a CPP of more than 60 (CPP = 70-10 mm Hg). If the brain appears to be edematous, then the ICP should be considered to be 20 mm Hg, and the MAP would need to be more than 80. Ideally, if an elevated ICP is suspected, then an ICP monitor should be inserted. One must also caution that CPP may be higher in PE/EC women than in normal women.^{6,7,9} Monitoring of ICP is not commonly done in most PE/EC patients; therefore, these basic guidelines can be followed. To assess ICP, TCD may be useful, and we will explore this concept later. Preliminary studies suggest that TCD can be used to determine CPP and the state of autoregulation in PE/EC and may therefore be useful to guide BP management. While intermittent agents can be effective for lowering BP, at times continuous infusions of antihypertensive agents are also needed.

For patients who remain in SE despite standard dosing of Mg,¹⁰ the transition of standard antiseizure medications may be needed. This can be done in several ways including the use of a loading dose of an anticonvulsant. In the past, phenytoin has been recommended as the initial drug,¹¹ but now, levetiracetam can also be given as an intravenous loading dose. Seizures may become controlled using this approach but may persist and take the form of SE.

Status epilepticus is the state of repeated or continuous seizure activity lasting for over 5 minutes. Status epilepticus is frequently nonconvulsive, so that there are no motor signs that the brain is seizing. The longer the seizures persist, the harder it is to stop them, and the more the damage to the brain. Hence, SE is a true emergency. There have been a number of treatments for SE, but two prospective randomized controlled trials have indicated that the best first drug is lorazepam, given intravenously. The treatment of refractory SE most commonly involves continuous infusions of deeply sedating agents such as midazolam, propofol, or pentobarbital. The continuous electroencephalography (cEEG) is used to monitor the biological effect of the treatment. Patients demonstrating SE may be treated with continuous midazolam infusion 0.5 to 2 mg/kg per hour to induce burst suppression. The treatment is then titrated to the EEG, and long-acting antiseizure

TABLE 146-2 Summary of the Treatment of Status Epilepticus in Eclampsia

| STAGE | MEDICATION | ENDPOINT |
|-------------------------------|---|---------------------------------|
| Brief seizure | Magnesium infusion | Clinical seizure control |
| Status epilepticus | Lorazepam, LEV or DPH, Mg | cEEG for seizure suppression |
| Refractory status epilepticus | IV midazolam or pentobarbital continuous infusion | cEEG for burst suppression coma |

The treatment may entail not only the use of magnesium but also treatments including continuous infusions of anesthetic drugs.

cEEG, continuous electroencephalography; DPH, phenytoin; IV, intravenous; LEV, Levetiracetam; Mg, magnesium.

medications are optimized. Table 146-2 shows the progression of interventions for seizures in PE/EC.

Most PE/EC patients with seizures are maintained on an antiseizure medication for the duration of critical illness. The longer-term treatment and total duration of antiseizure medications may vary and are beyond the scope of our discussion. This will likely need consultation with a neurologist for longer-term care and assessment.

STROKE AND BRAIN HEMORRHAGE IN PREGNANCY

Stroke is a potential complication of the late stages of pregnancy and can present to the ICU with either ischemic stroke or hemorrhagic stroke.^{2,12,13} Stroke frequently occurs in the context of a hypercoagulable state and has been thought to be related to EC. There are three common forms of stroke that can occur in pregnancy and may come to the attention of the intensivist: (1) cerebral sinus thrombosis (CST), (2) posterior reversible encephalopathy syndrome (PRES), and (3) intracerebral hemorrhage (ICH) related to coagulopathy including thrombotic thrombocytopenic purpura (TTP), as can be seen in a rare form of EC.^{2,12,13} These forms of stroke often can elicit severe brain edema, seizures, and coma, and present in extremis.

Cerebral sinus thrombosis, sometimes known as dural sinus thrombosis, is one of the most common forms of stroke in pregnancy.¹² The presentation is commonly subacute with progressive headache, somnolence, and then stroke-like signs. Brain imaging shows ICH with the classic locations of parasagittal white matter (Fig. 146-1). The brain is edematous and ICP is elevated. The treatment is centered on the reduction in ICP and includes systemic anticoagulation, hydration, and osmolar treatment. These patients are among the most critically ill pregnant patients with neurocritical illness. Diagnostic evaluation including MR venography is typically required. Systemic anticoagulation can be safely performed even in the setting of ICH.¹⁴ However, anticoagulation may not be enough, and invasive endovascular venous thrombectomy may be required.¹⁵ In the latter case, shielding of the fetus during angiography can be done. The use of anticoagulation is with intravenous heparin infusion with titration to moderate levels of anticoagulation. This is combined with hydration and osmolar therapy to enhance cerebral circulation. Monitoring for seizures, elevated ICP, and brain edema may be necessary if the brain edema is severe. Systemic hemodynamic management should be optimized for CPP, similar to the discussion for EC.

Posterior reversible encephalopathy syndrome is another potential complication of pregnancy.^{2,13} It may occur in the context of EC or CST, or be isolated. It is distinguished by imaging, typically MRI. The posterior parietal regions have extracellular brain edema noted on T2-weighted images, such as fluid-attenuated inversion recovery sequences. Posterior reversible encephalopathy syndrome can result from exposure to selected drugs or spontaneously during pregnancy.

FIGURE 146-1 ■ Case example of superior sagittal sinus thrombosis giving rise to an intracerebral hemorrhage. **A**, CT brain showing a brain hemorrhage and brain edema. **B**, CT venogram showing occlusion of the anterior portion of the superior sagittal sinus. CT, computed tomography.

The overlap with PE/EC is noteworthy. The treatment is strict reduction of BP to the normal range.

Coagulopathy-related ICH may occur during the later stages of pregnancy. This can occur with the HELLP¹⁶ (hemolysis, elevated liver enzymes, low platelets) syndrome, TTP, or as a result of embolism of amniotic fluid. Coagulopathy-related ICH patients are frequently in extremis, with elevated ICP, and are treated similarly to other patients with elevated ICP. Systemic correction of coagulopathy is required.

There are less common cerebrovascular events in pregnancy—namely, subarachnoid hemorrhage and reversible vasoconstriction syndrome. The latter is characterized by an abrupt onset of headache and cerebral vasospasm in the absence of an intracranial aneurysm. This is usually self-limited but may require induced hypertension and treatment of vasospasm, similar to the typical subarachnoid hemorrhage.

MONITORING AND TREATING THE NEUROLOGICALLY IMPAIRED PREGNANT PATIENT

The critically ill pregnant patient will frequently be neurologically impaired. This impairment may range from being delirious to comatose. Use of brain imaging should be encouraged for diagnostic specificity. However, monitoring the patient for seizures, elevated ICP, and cerebral ischemia is very important. Table 146-3 outlines some of the potential means for brain monitoring in the neurologic critically ill patient: (1) cEEG monitoring: cEEG monitoring consists of routine scalp EEG using 16 to 21 electrodes to monitor for seizures. Seizures are frequently nonconvulsive, and hence EEG is necessary to observe them. Monitoring for a minimum of 48 to 72 hours has been advocated by some to diagnose seizures, and monitoring for titration of seizure suppression is necessary for SE. (2) Transcranial Doppler (TCD): TCD detects flow velocity in the brain noninvasively and can be used to determine the relative cerebral blood flow. It can derive a pulsatility index (PI), which is a noninvasive measure of vascular resistance. The PI is directly proportional to ICP and can therefore be used as a noninvasive measure of ICP. A value of PI more than 1.5 is indicative of elevated ICP in the setting of a child-bearing-aged woman (Fig. 146-2). (3) Pupillometer: The pupillometer is an automated light source and high-speed digital video camera that measures the reaction time of the pupil constriction to light.¹⁷ The pupillometer provides a summary reading called the neurologic pupil index (NPI) that has been correlated with ICP. An NPI less than 3 in the setting of brain edema indicates the presence of elevated ICP. Figure 146-3 shows an example

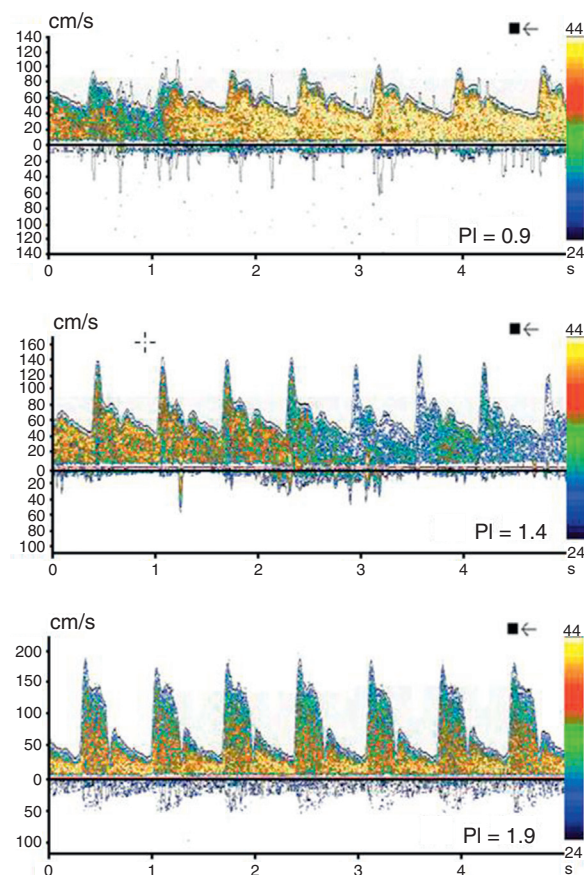

FIGURE 146-2 ■ Sequence of transcranial Doppler ultrasound of the cerebral circulation. The PI values are shown at the bottom right of each panel. The PI value increases from 0.9 to 1.9 across the panels, indicating worsening of brain edema and ICP; PI may be used as a noninvasive measure of ICP. ICP, intracranial pressure; PI, pulsatility index.

FIGURE 146-3 ■ Example of a nonconvulsive seizure detected on EEG monitoring. The generalized high-amplitude waves are similar to ventricular tachycardia and represent seizures.

TABLE 146-3

Common Tools Used to Monitor the Brain of Pregnant Women with a Central Nervous System Critical Illness

| MONITOR | SETTING | INDICATOR | INTERPRETATION |
|--------------|-------------------------------|---------------|----------------|
| EEG | Altered mental status or coma | Raw EEG | Seizure |
| TCD | PE/EC | Mean velocity | CBF |
| TCD | Coma | PI >1.5 | ICP |
| Pupillometer | Coma | NPi <3 | ICP |

CBF, cerebral blood flow; EEG, electroencephalography; ICP, intracranial pressure; NP_i, neurologic pupillary index; PE/EC, preeclampsia/eclampsia; PI, pulsatility index; TCD, transcranial Doppler ultrasound.

of TCD waveforms with increasing PI indicative of brain edema and elevated ICP.

CONCLUSION

The critical care of a pregnant patient with neurologic critical illness can be challenging. The main treatment considerations should be for

the welfare of the mother, especially in the later stages of pregnancy, when most presentations to the ICU occur. Consideration for the quick diagnosis of seizures, brain ischemia, and intracranial hypertension is most crucial in these patients.

KEY POINTS

1. Always suspect and rule out a venous sinus thrombosis in a pregnant patient presenting with acute neurologic symptoms.
2. Rapid diagnosis and control of seizures is a top priority for the pregnant patient.
3. Control of intracranial pressure and blood pressure is a key parameter in the pregnant patient with malignant hypertension and PRES.

ALTERED GLUCOSE REGULATION IN STRESS

At the end of the 19th century, Claude Bernard described a link between acute trauma and the development of hyperglycemia, irrespective of underlying diabetes. It was considered to be an adaptive stress response ensuring adequate glucose supply to obligatory glucose-consuming neurons, phagocytes, and reparative cells.^{1,2} Stress-induced hyperglycemia is evoked by integrated hormonal, cytokine, and nervous counterregulatory signals in glucose metabolic pathways. Essentially, hyperglycemia is due to insulin resistance in the liver and skeletal muscle. Hepatic insulin resistance leads to increased hepatic gluconeogenesis and glucose output.³ Decreased glycogen synthesis and a shift from insulin-dependent to non-insulin-dependent glucose uptake characterize skeletal muscle insulin resistance.⁴

In the acute phase of critical illness, increased levels of glucagon, cortisol, and growth hormone may jointly increase hepatic gluconeogenesis. In addition, the catecholamines epinephrine and norepinephrine released in response to acute injury promote hepatic glycogenolysis. The cytokines interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF) may directly or indirectly enhance both these hyperglycemic responses.⁵

The important exercise-stimulated glucose uptake in skeletal muscle completely disappears in critically ill patients because of immobilization. Insulin-dependent glucose uptake is also hampered through the combined inhibition of glucose transporter-4 (GLUT-4) and glycogen synthase activity.^{6,7} Although some studies have shown decreased glucose oxidation⁸ through pyruvate produced by glycolysis, others have demonstrated an opposite effect during critical illness.⁹ The decrease in insulin-dependent glucose uptake in skeletal muscle is completely offset by a strong increase in total body glucose uptake, of which the mononuclear phagocyte system in the liver, spleen, and ileum are the main receivers.¹⁰ However, in skeletal muscle, non-insulin-dependent glucose uptake is also increased by the increased expression of GLUT-1.^{11,12} The overall increased peripheral glucose uptake¹³ in light of hyperglycemia underscores the pivotal role of increased hepatic glucose production during critical illness, which cannot be suppressed by exogenous glucose.¹⁴

The role of adipose tissue in the regulation of glucose metabolism during critical illness has been neglected. Nevertheless, in diabetes mellitus, adipose tissue strongly modulates insulin resistance as it is regarded to be an insulin-dependent glucose uptake organ. Recent studies have revealed that during critical illness, adipose tissue undergoes major changes.¹⁵ Possibly stimulated by illness-induced macrophage infiltration, adipocytes become more numerous and smaller and have an increased expression of the non-insulin-dependent glucose transporters GLUT-1 and GLUT-3. The levels of GLUT-4 remain unaltered. As such, adipose tissue is reprogrammed during critical illness to facilitate glucose uptake, independent of circulating insulin levels.

HYPERGLYCEMIA IN CRITICALLY ILL PATIENTS

In normal individuals, blood glucose levels are tightly regulated within the narrow range of 60 to 140 mg/dL (3.3-7.7 mmol/L), both in fed and fasted states. The World Health Organization (WHO) defined diabetic hyperglycemia as a fasting blood glucose concentration of

126 mg/dL (7 mmol/L) or higher and fed blood glucose levels higher than 200 mg/dL (11.1 mmol/L). In their 2006 guidelines, the WHO functionally defined *normoglycemia* as glucose levels associated with a low risk of developing diabetes or cardiovascular disease. Unlike the diagnostic criteria for diabetes mellitus, no clear guidelines have been established for defining hyperglycemia in critically ill patients. This explains the variations in the reported prevalence of hyperglycemia in critically ill patients.

However, stress hyperglycemia is also associated with adverse outcome in several critically ill patients. More precisely, a large cohort study of over 66,000 critically ill patients revealed a J-curved relationship between on-admission blood glucose levels and the risk of mortality, with the nadir between 100 and 150 mg/dL (5.6-8.3 mmol/L).¹⁶ In patients with an acute coronary syndrome, a similar association was observed, with the lowest risk of mortality at blood glucose levels between 80 and 100 mg/dL (4.4-5.5 mmol/L).¹⁷⁻²⁰ Importantly, in patients with established diabetes mellitus prior to critical illness or an acute coronary syndrome, the relationship between hyperglycemia and mortality was significantly blunted and somewhat shifted toward higher blood glucose level¹⁷ (Fig. 147-1).

Until recently, it was considered state of the art to tolerate blood glucose levels of up to 220 mg/dL (12 mmol/L) in fed critically ill patients. It was even suggested that this moderate hyperglycemia in critically ill patients was beneficial to organs such as the brain and blood cells, which rely solely on glucose for their energy supply and do not require insulin for glucose uptake. Treatment of blood glucose levels higher than 12 mmol/L was primarily due to the occurrence of hyperglycemia-induced osmotic diuresis and fluid shifts. Further, from the literature on diabetes, it is known that uncontrolled and pronounced hyperglycemia predisposes to infectious complications.²¹ In patients with known diabetes mellitus, more attention was paid to blood glucose levels and consequently was more strictly controlled. This approach contrasts—in hindsight—with the blunting of the J-shaped relationship between glycemia and mortality risk. Observational studies have also revealed that hyperglycemia in patients with established diabetes mellitus has an at least threefold higher risk of mortality than patients with known diabetes.²²

MAINTENANCE OF NORMOGLYCEMIA IN THE INTENSIVE CARE UNIT

The Leuven Studies

In 2001, a large prospective, randomized, controlled trial (RCT) was the first to challenge the classic dogma of beneficial stress hyperglycemia.²³ It examined the effect of tight glycemic control (TGC) with intensive insulin therapy on the mortality and morbidity of critically ill patients. Over a 1-year period, 1548 mechanically ventilated patients who were admitted to the intensive care unit (ICU), predominantly after extensive or complicated surgery or trauma, were randomly allocated to either intensive insulin therapy with blood glucose levels kept tightly between 80 and 110 mg/dL (4.5-6.1 mmol/L) or the conventional approach, which recommended insulin therapy only if blood glucose levels exceeded 12 mmol/L. The intervention of TGC comprised accurate arterial blood glucose measurements by a blood gas analyzer and a reliable continuous infusion of insulin exclusively via a central venous line using an accurate syringe-driven infusion pump. The fine insulin dose adaptations were performed by trained

FIGURE 147-1 ■ J-shaped association of blood glucose levels with mortality risk in critically ill patients. In patients without diabetes mellitus, hyperglycemia shows an almost linear relationship with mortality risk. Hypoglycemia is associated with an even steeper increase in mortality risk. Normoglycemia during critical illness conveys the lowest risk of dying. In patients with established diabetes, the J-shaped curve is significantly flattened out.

bedside nurses and based on guidelines that require a high level of intuitive and anticipatory decision making.²³ In this study, patients were kept in a nonfasting state at all times. Dextrose 20% was administered on the first day (192 g glucose over 24 hours, or 768 kcal/d). Thereafter, enteral nutrition was started, with the daily amount progressively increased as tolerated. When enteral nutrition was insufficient, early supplemental parenteral nutrition was given, resulting in administration of 1100 nonprotein kcal/d on average.

Intensive insulin therapy, resulting in the administration of 1100 nonprotein kcal/d on average, lowered ICU mortality from 8% to 4.6% (absolute risk reduction [ARR], 3.4%) and in-hospital mortality from 10.9% to 7.2% (ARR, 3.7%). The effect occurred particularly in the population with prolonged critical illness, among whom mortality was reduced from 20.2% to 10.6%. Even patients in the conventional insulin treatment schedule with only moderate hyperglycemia (110–150 mg/dL) showed higher mortality than those in the strict glycemic control schedule.²⁴ Intensive insulin therapy also had a major effect on morbidity. It decreased the duration of ventilatory support and ICU stay, reduced the need for blood transfusions, and lowered the incidence of bloodstream infections and excessive inflammation. Even more striking, intensive insulin therapy caused a highly significant decrease in the development of critical illness polyneuropathy and acute kidney failure.

Subsequently, the effect of TGC was tested in a medical ICU setting by the same group.²⁵ The difference in in-hospital mortality, 40.0% in the control group and 37.3% in the intervention group, was not statistically significant in an intention-to-treat analysis of the 1200 included patients. However, in patients who stayed in the ICU for 3 or more days, in-hospital mortality was reduced from 52.5% to 43.0% by TGC. Intensive insulin therapy also reduced morbidity (incidence of acute kidney failure, weaning off the ventilator, ICU/hospital stay), but not as strikingly as that in the surgical study. This was, in part, explained by a larger fraction of patients in medical ICUs who were admitted with established organ damage, possibly reducing the opportunity of prevention by glucose lowering.²⁶ The fact that intensive insulin therapy to normal-for-age blood glucose targets in mainly postoperative pediatric critically ill patients reduced mortality by an ARR of 3% may further corroborate this finding.²⁷

The downside of TGC has been the increase in the incidence of hypoglycemia (blood glucose levels <40 mg/dL [<2.2 mmol/L]) despite improving patient outcome. In the Leuven studies, 5.1% (surgical ICU), 18.7% (medical ICU), and 25% (pediatric ICU) of patients

randomized to TGC experienced at least one episode of hypoglycemia. To date, long-term follow-up studies to gauge the impact of brief hypoglycemia on neurocognitive function are lacking. In addition, it is possible that fluctuations in glucose levels, such as those induced by insulin therapy based on inaccurate glycemic monitoring or by over-correction of hypoglycemia, may be more deleterious than those induced by hypoglycemia by itself. Such aspects remain to be investigated in greater detail.

The Initial Repeat Studies

Two European multicenter studies designed to assess whether intensive insulin therapy exerts benefits, with mortality as the primary endpoint, failed to reproduce the Leuven findings. The Volume substitution and Insulin therapy in severe SEpsis (VISEP) (N = 537) trial was designed as a four-arm study to assess the difference between two choices of fluid resuscitation (10% pentastarch versus modified Ringer's lactate) and the efficacy and safety of intensive insulin therapy in patients with severe sepsis and septic shock.²⁸ In this study, blood glucose targets comparable to the Leuven studies were set out for the intervention (80–110 mg/L) and control (180–200 mg/dL) groups. Likewise, insulin administration and blood glucose measurements had been standardized. Nevertheless, the insulin arm of the study was stopped early after 488 patients had been included because the rate of hypoglycemia (12.1%) in the intensive insulin therapy group was considered unacceptably high and may have been associated with higher mortality. Then, at the first planned interim analysis, the fluid resuscitation arm of the study was also suspended because of increased risk of organ failure in the 10% pentastarch arm. The primary endpoint 90-day mortality was 39.7% in the intensive treatment arm and 35.4% in the conventional treatment arm.

The GLUCONTROL multicenter randomized controlled trial (RCT) (N = 1101) investigated whether tight glycemic control (80 and 110 mg/dL) with intensive insulin therapy versus an intermediate target for blood glucose (140–180 mg/dL [7.8–10.0 mmol/L]) improved survival in a mixed population of critically ill patients.²⁹ This study was also stopped early because the target glycemic control was not reached and the incidence of hypoglycemia was 9.8%. ICU mortality did not differ between the intensive insulin therapy group (17.2%) and the control group (15.3%).

Two single-center studies in a mixed medical/surgical ICU population, both smaller than the Leuven studies, followed and were unable to reproduce any significant mortality benefit.^{30,31} In contrast, a number of small RCTs in selected subpopulations, mostly focusing on morbidity as the primary endpoint, as well as several larger implementation studies, revealed improved outcomes as the Leuven studies did.^{32–35}

NICE-SUGAR

All the studies described were in fact statistically underpowered to detect a reasonable mortality difference. To address this issue, the Normoglycemia in Intensive Care Evaluation and Survival Using Glucose Algorithm Regulation (NICE-SUGAR) included 6100 patients from over 41 participating centers.³⁶ This study compared a blood glucose target of below 108 mg/dL (<6.0 mmol/L) versus “usual care,” which meant an intermediate blood glucose target of 140 to 180 mg/dL (8 to 10 mmol/L). As the result of the Leuven studies, clinicians had become aware of the negative impact of hyperglycemia, so tolerating higher glucose levels was considered unacceptable or even unethical by clinicians and investigators. The aim of NICE-SUGAR, therefore, was to assess whether further lowering blood glucose levels to less than 108 mg/dL (<6.0 mmol/L) in a broad context of clinical practice in ICUs, predominantly located in Australia and New Zealand, and using the normal daily clinical practice tools available would exert additional benefit. Contrary to expectations, NICE-SUGAR revealed that targeting 108 mg/dL with insulin increased 90-day mortality from 24.9% to 27.5% compared to the 140- to 180-mg/dL (8–10 mmol/L) glucose target. Excess deaths were attributed to cardiovascular causes.

COIITSS

Patients with septic shock requiring administration of glucocorticoids are faced with a high mortality risk; the severity of illness and glucocorticoid treatment makes hyperglycemia common. Therefore, this would be an optimal population in which to study whether TGC could reduce mortality. In the Corticosteroids and Intensive Insulin Therapy for Septic Shock (COIITSS) multicenter study, 509 patients were randomized to either intensive insulin therapy aiming for blood glucose levels between 80 and 110 mg/dL or conventional insulin therapy.³⁷ In the latter group, an intermediate target was used as the physicians were recommended to follow the 2004 Surviving Sepsis Campaign Guidelines (blood glucose levels <150 mg/dL [8.3 mmol/L]). Hospital mortality in the intensive insulin therapy group (45.9%) did not differ from that in the conventional group (42.9%). Poor separation of blood glucose levels between the study groups, and the small size of the study may have made it difficult to detect any treatment effect of TGC.

Meta-analyses

Nowadays, practice guidelines are ideally based on systematic reviews and meta-analyses. The two most recent meta-analyses showed that in critically ill adult patients, TGC did not significantly reduce hospital mortality but was associated with an increased risk of hypoglycemia.^{38,39} However, TGC may be beneficial to patients admitted to surgical ICUs.

CRITICAL APPRAISAL OF THE EVIDENCE FOR TIGHT GLYCEMIC CONTROL IN THE ICU

Given that the effect of controlling blood glucose levels during critical illness ranges from beneficial to no effect to potentially harmful, most clinicians are now in agreement that blood glucose levels do, in fact, play a role in patient outcome. The pre-2001 era, where blood glucose levels were rarely measured in critically ill patients, has passed. However, discrepancies in study results have made it difficult to make strong recommendations. Likewise, consensus statements on the glycemic management of hospitalized patients by the American Association of Clinical Endocrinologists and the American Diabetes Association have changed significantly over the past years.⁴⁰ While the 2004 and 2006 statements recommended stricter targets for glycemic management in the ICU, in 2009, it was advised that the starting threshold for intravenous insulin therapy in the ICU be 180 mg/dL (10 mmol/L). Once started, blood glucose levels should be maintained between 140 and 180 mg/dL (7.8–10 mmol/L). Somewhat lower levels may be appropriate in selected patient populations. Targets below 110 mg/dL (<6.1 mmol/L) are not recommended.

Still, more can be learned from the differences between the Leuven proof-of-concept studies and the subsequent repeat trials.⁴¹ First, “normoglycemia” was compared with distinct “control” targets (140–180 mg/dL or 8–10 mmol/L in NICE-SUGAR and GLUCONTROL; 180–215 mg/dL or 10–12 mmol/L in Leuven), making the studies fundamentally different. The control group in the Leuven studies reflected the assumption of hyperglycemia as a potentially beneficial adaptation. Hence, a “do-not-touch” approach unless glucose exceeded the renal threshold of 215 mg/dL was used in this group. In contrast, the NICE-SUGAR trial was executed in the “flatter” part of the observational glycemia-mortality risk curve, with 70% of the patients in the control group receiving insulin treatment to target an intermediate blood glucose level of 140 to 180 mg/dL (8–10 mmol/L) (Fig. 147-2).^{16–19} The control group in the NICE-SUGAR trial, as a result of the changed usual care, already could have benefited from reducing blood glucose level as compared with the control group in the Leuven studies. The lower observed mortality than the carefully documented expected mortality (24.9% vs. 30%, respectively) in the NICE-SUGAR control group suggests that there was already such a benefit in the control group.

FIGURE 147-2 ■ Relationship of blood glucose levels with mortality in the NICE-SUGAR and Leuven studies. Comparing tight glycemic control with “usual care” strongly depends on mortality risk in the control group. In the Leuven proof-of-concept studies, tight glycemic control was compared with the usual care of tolerating hyperglycemia up to the renal threshold (215 mg/dL). The control group in the NICE-SUGAR trial targeted intermediate blood glucose levels (145–180 mg/dL).

Second, the level of therapy compliance, in this case, the degree of success in reaching and maintaining the preset target range for glucose in the intervention group, as well as the degree of overlap with the control group, varied greatly among the studies. The methodologic aspects of glucose measurement and the level of expertise of the nursing team with blood glucose control in the Leuven studies may have played a key role. In the Leuven studies, 70% of the patients in the intervention group were on average on target,⁴² whereas this was much less than 50% in the NICE-SUGAR trial and in several of the other repeat studies. This could be important as a recent meta-analysis suggested that studies that actually managed to adequately achieve the blood glucose target showed a reduced mortality, whereas those that did not succeed in reaching the target reported no benefit or even increased mortality.^{38,43} Maintaining normoglycemia may be more feasible in patients after surgical critical illness than in those with medical illnesses.

Third, a requirement for safe insulin dose adjusting to reach and maintain normoglycemia should be a standardized, accurate glucose measurement technology. In the NICE-SUGAR trial, a variety of glucose meters were allowed, whereas most of them have recently been shown to be unsuitable for this purpose.⁴⁴ Accuracy of certain glucometers has been shown to be extremely poor in the ICU setting, and the wide error goes in the opposite direction for the low and high glucose ranges, making it impossible to use them for targeting a very narrow glucose range.^{45,46} In addition, varying sampling sites (arterial, venous, and capillary) were accepted in the context of routine clinical practice, and these also have led to erroneous results for blood glucose levels.⁴⁷ Inaccuracy of glucose measurement may have misguided insulin titration and thereby induced (undetected) hypoglycemia and large blood glucose fluctuations. Avoiding highly variable blood glucose levels requires experience and thus has a learning curve, which is inherent with complex interventions.

Fourth, feeding strategies differed in the major studies. The substantially higher amounts of parenteral nutrition in the Leuven studies, although still below normal caloric requirements on average, may have increased the severity of stress-induced hyperglycemia, and thus, the intervention may have been, in part, directed to counteract this side effect of parenteral nutrition. In the NICE-SUGAR trial, feeding relied almost exclusively on the enteral route (80 kcal intravenous glucose on

the first day; on average, a total of 880 kcal/d), whereas in the Leuven studies, early parenteral nutrition (768 kcal on the first day) supplemented insufficient enteral feeding, resulting in an average of 1100 kcal/d for adult patients. Insulin treatment in a nutritionally deprived state early in the disease course, as in the NICE-SUGAR trial as a result of their feeding guidelines, may have been deleterious by evoking a global substrate deficit via insulin-induced counteracting of proteolysis, lipolysis, glycogenolysis, and gluconeogenesis, which could be vital in starvation.

Fifth, in a setting where hyperglycemia is triggered by surgery or trauma, the equivalent of acute ischemia/reperfusion, the delay between the onset of hyperglycemia and the start of glycemic control is short. In contrast, when ICU patients already suffered from chronic illness prior to ICU admission and hyperglycemia was present for a longer time, adaptive changes to protect cells against elevated extracellular glucose levels may have been induced, such that acute lowering of blood glucose levels may be harmful. Alternatively, the time window for prevention of toxicity may have passed and irreversible damage done.⁴⁸ Such a mechanism was suggested by the pooled analyses of the two Leuven studies⁴² and by the different results of RCTs on glucose control in patients with type 2 diabetes.⁴⁹⁻⁵⁴

Finally, insulin therapy induces a shift of potassium from extracellular to the intracellular compartments. This may induce hypokalemia and hypokalemia-induced arrhythmias. By using arterial blood and an accurate point-of-care blood gas analyzer for glucose monitoring with each blood glucose check, potassium levels can be measured and corrected when needed.

All these differences may have contributed to the different outcomes in different studies. It has become clear that results from single-center, proof-of-concept studies cannot simply be repeated in large multi-center effectiveness trials, particularly when studying the effects of a complex intervention, which is regularly incompletely implemented in the repeat studies.⁵⁵ Hence, in reality, such studies did not investigate the same intervention as the proof-of-concept study.

BIOLOGICAL RATIONALE FOR TIGHT GLYCEMIC CONTROL

Research using human material, animal models, and in vitro systems has unraveled potential mechanistic explanations for the beneficial effects of TGC (Table 147-1). As in diabetes mellitus, insulinization to lower blood glucose levels exerts its effects on an array of biological pathways. Striving for metabolic control and inhibiting excess inflammation and mitochondrial damage seem to be of chief importance. Further molecular biology research will not only be essential to fine-tune TGC with other metabolic treatment strategies but also contribute to the quest to explain the potential harm of glucose lowering in critical illness.

Implications for Daily Practice

The failure to repeat the results from well-controlled, meticulously executed, proof-of-concept studies in large pragmatic confirmation trials has indicated that TGC is not yet ready to be broadly implemented in every ICU across the globe (Fig. 147-3). This does not undermine the scientific validity of the benefits of TGC in critically ill patients. Blood glucose levels should be normalized as much as safely

possible without causing a too rapid lowering of blood glucose levels, without an increase in the incidence of hypoglycemia, and without large blood glucose fluctuations. Therefore, it is advisable to gradually tighten glycemic control under diligent monitoring of the safety aspects. Nevertheless, three conditions should always be met:

1. Accurate and frequent blood glucose measurements as a reliable invasive, continuous glucose sensor are not yet available. Capillary blood samples are unreliable in the ICU and should never be used. Blood glucose measurements on on-site blood gas analyzers are the currently preferred devices. However, the use of a single handheld blood glucose meter with an acceptable error range and using arterial blood may be an alternative.
2. Continuous intravenous insulin administration using accurate syringe pumps
3. Thorough training of ICU healthcare providers (i.e., physicians and nurses) in the execution of the complex intervention of TGC. This stimulates intuitive and anticipatory decision making, as computer algorithms to assist in TGC still have to show their benefit on patient outcome.

CONCLUSION

The discrepancy in study quality and results does not permit clear-cut, evidence-based recommendations for one optimal blood glucose target in heterogeneous ICU populations and settings. One could recommend keeping blood glucose levels between 80 and 130 mg/dL (4.4-7.2 mmol/L). A broader target range would partially compensate for the inaccuracies of handheld blood glucose meters and allow more inexperienced ICU teams to implement targeted glycemic control. Trying to steer blood glucose levels within a narrow range without proper measurement devices and experience may cause large blood glucose variations and hypoglycemia. Therefore, frequent and reliable measurements of blood glucose levels remain mandatory.

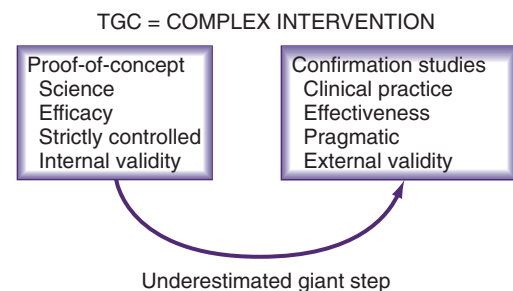

FIGURE 147-3 ■ Difference between proof-of-concept studies and confirmation studies. Proof-of-concept studies are driven by the specific question of whether a certain intervention may work (efficacy). The intervention is tested in a highly controlled setting to minimize confounding factors, resulting in high internal validity. In contrast, confirmation studies wonder whether this intervention would work in clinical practice (effectiveness). Potential confounders are allowed to test the generalizability and pragmatic character of the intervention (external validity). When testing complex interventions, these differences between proof-of-concept and confirmation studies in their aim and setup are often underestimated.

KEY POINTS

1. "Stress hyperglycemia" results from the interplay of an increased hepatic glucose output and a decreased insulin-dependent glucose uptake in skeletal muscle. Adipose tissue seems to shift from insulin-dependent to insulin-independent glucose uptake.
2. Stress hyperglycemia was once regarded as a beneficial response. Nevertheless, large observational studies have shown a J-shaped association of blood glucose levels with mortality risk in critically ill patients. In patients with established diabetes mellitus, this relationship is significantly blunted. As such, new-onset hyperglycemia is associated with a higher mortality risk than hyperglycemia in patients with diabetes mellitus.
3. In 2001, a large proof-of-concept study challenged the classic dogma that so-called stress hyperglycemia of up to 12 mmol/L (220 mg/dL) is a beneficial response in nondiabetic patients.

Glycemic control at less than 6.1 mmol/L (110 mg/dL) with exogenous insulin reduced mortality and morbidity among critically ill patients in a surgical ICU.

4. Two other single-center studies from the Leuven investigators showed similar effects of tight glycemic control in medical and pediatric ICU patients. However, several repeat studies could not confirm the beneficial effects of tight glycemic control. The NICE-SUGAR multicenter trial even showed an increased mortality risk by tight glycemic control.
5. Differences in patient populations, blood glucose control in the "usual care" group, nutritional strategies, and methodology of blood glucose measurements may all have contributed to the variability in the treatment effect of tight glycemic control.

ANNOTATED REFERENCES

During the stress response, the central nervous system (CNS) induces activation of both the sympathoadrenergic system (by release of catecholamines) and the hypothalamic-pituitary-adrenal (HPA) axis (by release of steroid hormones, glucocorticoids (GCs), and mineralocorticoids), with the target of maintaining homeostasis by influencing metabolic, cardiovascular, immunologic, and endocrine functions. In this context, the adrenal gland plays a key role, combining the location for synthesis and expression of catecholamines, GCs, androgenic hormones, and factors of the renin-angiotensin-aldosterone (RAA) system. Acute and chronic inflammatory diseases include stimulation of the HPA axis by the immune system, thereby leading to morphologic and functional changes, especially of the adrenal cortex. This phenomenon has been described for acute infectious diseases as well as for sepsis and septic shock.

Over 50 years ago, the seminal observation was made that administering an adrenal cortical steroid extract to a patient with progressive, active rheumatoid arthritis slowed progression of the disease. This soon led to the development of synthetic adrenal cortical steroids, which gained a remarkable reputation in the treatment of a wide range of inflammatory and autoimmune disorders. However, it soon became apparent that this efficacy did not come without a cost in terms of potentially serious adverse effects. In patients with sepsis and septic shock, negative results of trials with high doses of GCs evoked skepticism over the years. Meanwhile, several randomized trials revealed contradictory results with low doses of corticosteroids in patients with septic shock. Hence, there is still controversy about which patients profit best from this therapy and how to define and evaluate adrenal gland disorders.¹⁻⁴

ANATOMY OF THE ADRENAL GLAND

The two paired adrenal glands are located in the retroperitoneal soft tissue near the top of each kidney. In neonates, the adrenal glands are relatively large (approximately one-third of the kidney's size) compared with other organs. In the postnatal period, the cortex portion shrinks, leading not only to a relatively but also an absolutely smaller size of the organ. In adults, each adrenal gland weighs 4 to 5 g, has a flat form with a sagittal diameter of less than 1 cm, a transverse diameter of 3 cm, and a craniocaudal diameter of 4 to 5 cm. The right gland has a triangle/pyramid-like shape, whereas the left gland has a half-moon shape.

Circulatory supply to the adrenals, with a flow rate of about 5 mL per minute, is maintained by up to 50 arterial branches from the aorta, renal arteries, and inferior phrenic arteries for each gland. Blood flow is directed from the capsule into the subcapsular arteriolar plexus through the cortex toward the medulla, where a single vein drains the blood entering the vena cava or the renal vein. Direct blood supply to the medulla is maintained by medullary arteries.

The adrenal cortex receives afferent and efferent innervation. Direct contact of nerve terminals with adrenocortical cells has been suggested, and chemoreceptors and baroreceptors present in the adrenal cortex infer efferent innervation. Diurnal variation in cortisol secretion and compensatory adrenal hypertrophy are influenced by adrenal innervation. Splanchnic nerve innervation has an effect in regulating adrenal steroid release. The adrenal medulla secretes the catecholamines epinephrine and norepinephrine, both of which affect blood

pressure, heart rate, sweating, and other activities regulated by the sympathetic nervous system. The adrenal cortex is divided into three layers: (1) the zona glomerulosa, just under the capsule, (2) the zona fasciculata, the middle layer, and (3) the zona reticularis, the innermost, net-like patterned area with reticular veins draining into medullary capillaries. The zona glomerulosa exclusively produces the mineralocorticoid aldosterone; the zonae fasciculata and reticularis produce GCs and androgens.⁵

PHYSIOLOGY OF THE HYPOTHALAMIC-PITUITARY-ADRENAL AXIS

The adrenal glands are part of a complex system that produces interacting hormones to maintain physiologic integrity, especially during the stress response.^{6,7} This system, the *HPA axis*, includes the hypothalamic region that produces corticotropin-releasing hormone (CRH), which stimulates the pituitary gland. The pituitary gland is composed of two major structures: the adenohypophysis (anterior pituitary) and neurohypophysis (posterior pituitary). The anterior pituitary is responsible for the secretion of corticotropin (adrenocorticotrophic hormone [ACTH]), thyroid-stimulating hormone (TSH), growth hormone (GH), β -lipotropin, endorphins, prolactin, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). The posterior pituitary secretes vasopressin (antidiuretic hormone [ADH]) and oxytocin. Corticotropin regulates the production of corticosteroids by the adrenal glands. Hypothalamic neurons receive input from many areas within the CNS; they integrate these inputs and initiate an output to the anterior pituitary via the median eminence. The median eminence secretes releasing hormones into a hypophyseal portal network of capillaries that connect the median eminence with the pituitary hormones.

The anterior pituitary gland secretes corticotropin (ACTH) under stimulation from hypothalamic CRH. ACTH, in turn, stimulates the synthesis and release of GCs, mineralocorticoids, and androgenic steroids from the adrenal gland. In terms of a feedback loop, ACTH release is inhibited by GCs, which act on both the pituitary corticotrophic cells and hypothalamic neurons. ACTH is also released during stress, independent of the circulating serum cortisol level. CRH, vasopressin, and norepinephrine act synergistically to increase ACTH release during stress. Endorphinergic pathways also play a role in ACTH regulation. Acute administration of morphine stimulates release of ACTH, while chronic administration blocks secretion of ACTH. ACTH and cortisol are secreted normally in a diurnal pattern, with lowest concentrations between 10:00 PM and 2:00 AM and highest levels around 8:00 AM. Samples obtained at different times can provide useful dynamic information regarding HPA function. Loss of diurnal rhythm may indicate hypothalamic dysfunction.

The HPA axis is stimulated not only by physical or psychic stress but also by peptides such as ADH and cytokines. Thus, the HPA axis plays an important role during infections and immunologic disorders.^{8,9} Via interaction with the RAA system regulating fluid and salt balance, synthesis of androgens (e.g., dehydroepiandrosterone) with a possible impact on immunomodulation and the sympathoadrenergic system, the HPA axis is probably the most important organ of the stress response. Stimulation of the immune system by infections induces the release of proinflammatory cytokines such as tumor necrosis factor

alpha (TNF- α), interleukin (IL)-1 β , or IL-6. Following a cascade, these cytokines stimulate both the hypothalamus and the anterior pituitary gland, which ultimately leads to the release of GCs. IL-6 is also able to induce a steroid release directly from the adrenal gland. The adequate increase of GC levels during inflammation is a crucial factor for an appropriate stress response. In acute infections, this release maintains metabolic and energy integrity. If the process is chronic, the HPA axis develops an adaptation, which induces typical clinical manifestations such as hypercatabolic states, hyperglycemia, and suppression of androgens, growth, and thyroid hormones. These changes, however, may increase the risk of secondary infections. Increased cortisol levels suppress higher regulatory levels of the HPA axis in terms of a negative feedback loop. Hence, after major surgery or during sepsis and septic shock, high cortisol and low ACTH levels are detectable.^{10,11} Even the infusion of dexamethasone or CRH is not able to suppress increased cortisol levels in these patients.^{12,13} Several investigations have demonstrated that adrenal cortisol synthesis in critically ill patients is not regulated by ACTH but by paracrine pathways via endothelin, atrial natriuretic peptide, or cytokines such as IL-6.¹⁴⁻¹⁶ IL-6 directly induces the adrenal cortex to release cortisol, which, in chronic courses, can worsen the prognosis.¹⁷

CELLULAR RESPONSE TO ADRENOCORTICAL HORMONES AND RELATED DRUGS

Cortisol, the major free circulating adrenocortical hormone, is a hydrophobic hormone and circulates in the bloodstream bound to protein. Cortisol-binding globulin (or transcortin)-protein complexes account for about 95% of circulating cortisol, but only the free form is biologically active with a plasma half-life of 60 to 120 minutes. Cortisol is metabolized by hydroxylation in the liver, and metabolites are excreted in the urine. Steroid hormones enter the cytoplasm of cells where they combine with a receptor protein. Metabolic, immunologic, and hemodynamic responses to adrenocortical steroid hormones are regulated in a very complex manner that includes transactivation, transcription, posttranscriptional/translational regulation, and nongenomic effects. The immediate nongenomic effects of steroid hormones are primarily attributed to mineralocorticoids (aldosterone), with rapid activation of the sodium-proton exchanger, increase in intracellular Ca⁺⁺ levels, and activation of second messenger pathways.^{18,19} A randomized trial in patients during cardiac catheterization revealed that within minutes after aldosterone injection, cardiac index and arterial pressure increased significantly for 10 minutes and returned to baseline thereafter.²⁰ Interestingly, the genomic effects of aldosterone seemed to be mediated by binding to GC receptors (GRs) and not to mineralocorticoid receptors.²¹ There is evidence that GC, like cortisol, also modulates immune functions by rapid, nongenomic effects via nonspecific interactions with cellular membranes and specifically binding to membrane-bound GRs.²² Nonspecific membrane effects have been demonstrated for inhibition of sodium and calcium cycling across plasma membranes by impairing Na⁺/K⁺-ATPase and Ca⁺⁺-ATPase. Moreover, the rapid activation of lipocortin-1 and inhibition of arachidonic acid release after GC were independent of GR translocation. Finally, high-sensitivity immunofluorescence staining revealed membrane-bound GRs on circulating B lymphocytes and monocytes.²²

The multiple mechanisms by which GCs modulate cellular responses include mainly genomic pathways.²³⁻²⁵ Nongenomic effects are thought to account for immediate immune effects of high doses of GC, whereas membrane-bound receptors probably mediate low-dose GC effects. The classic model is that GCs bind to the cytoplasmic ligand-regulated GC receptor alpha (GR α), which is an inactive multiprotein complex consisting of two heat shock proteins (hsp90) acting as molecular chaperones, as well as other proteins (Fig. 148-1). Upon GC binding to GR α , a conformational change causes dissociation of hsp90, with subsequent nuclear translocation of GR α homodimers, binding of

GR α to GC response elements (GREs) of DNA, and transcription of responsive genes (transactivation) such as lipocortin-1 and β_2 -adrenoreceptors. Alternatively, GR α may bind to negative GRE (nGRE) and repress transcription of genes (transrepression) such as pro-opiomelanocortin (POMC). More important, transrepression without direct binding of GR α to GRE by protein-protein interactions of GR α with transcription factors, nuclear factor kappa B (NF- κ B), and AP-1 has been recognized as a key step by which GC suppresses inflammation.²⁶ In turn, synthesis of TNF- α , IL-1 β , IL-2, IL-6, IL-8, inducible nitric oxide synthase (iNOS), cyclooxygenase (COX)-2, cell adhesion molecules, and growth factors is inhibited, and apoptosis promoted.²⁷ In addition, NF- κ B repression may be mediated by GC-induced upregulation of the cytoplasmic NF- κ B inhibitor, I κ B α (see Fig. 148-1), which prevents translocation of NF- κ B.²⁸ Clinical investigations provide support for the presence of endogenous GC inadequacy in the control of inflammation and peripheral GC resistance.²⁹ With GC treatment, the intracellular relations between the NF- κ B and GR α signaling pathways change from an initial NF- κ B-driven and GR α -resistant state to a GR α -sensitive one. However, data are conflicting and probably do not explain the early (<2 hours) suppressive effects of GC but may account for the longer-term dampening effect of GC on inflammatory processes.²³

Besides transcriptional regulation, posttranscriptional, translational, or posttranslational processes have been described for GC-induced modulation of COX-2, TNF- α , GM-CSF, IL-1 β , IL-6, IL-8, and interferon gamma (IFN- γ).²³ Furthermore, GCs act at multiple levels to regulate iNOS expression via (1) decreased iNOS gene transcription and mRNA stability, (2) reduced translation and increased degradation of the iNOS protein by the cysteine protease, calpain,³⁰ (3) limitation of the availability of the NOS cofactor, tetrahydrobiopterin, (4) reduced transmembranous transport and de novo synthesis of the NOS substrate, L-arginine, and (5) lipocortin-1-induced inhibition of iNOS.^{31,32} Together, these complex mechanisms result in the ability of GC to inhibit inflammation and to stabilize hemodynamics. Finally, GRs have been found in nearly every nucleated cell in the body, and since each cell type has specific responses to GC, it follows that GCs have many effects in the body, equally true of endogenously produced GC hormones or exogenously administered GC medications. Both increase hepatic production of glucose and glycogen and decrease peripheral use of glucose. Steroids also affect fat and protein metabolism. They increase lipolysis both directly and indirectly by elevating free fatty acid levels in the plasma and enhancing any tendency toward ketosis. GCs further stimulate peripheral protein metabolism, using the amino acid products as gluconeogenic precursors.

DEFINITIONS OF ADRENAL INSUFFICIENCY

Adrenal glands may stop functioning when the HPA axis fails to produce sufficient amounts of the appropriate hormones. *Primary adrenal insufficiency* is defined by the inability of the adrenal gland to produce steroid hormones even when the stimulus by the pituitary gland via corticotropin is adequate or increased. Primary adrenal insufficiency affects 4 to 6 out of 100,000 people. The disease can strike at any age, with a peak between 30 and 50 years, and affects males and females about equally. In 70% of cases, the cause is a primary destruction of the adrenal glands by an autoimmune reaction ("classical" Addison's disease or autoimmune adrenalitis), with about 40% of patients having a history of associated endocrinopathies. Most adult patients have antibodies against the steroidogenic enzyme, 21-hydroxylase,³³ but their role in the pathogenesis of autoimmune adrenalitis is uncertain. In the other 30%, the adrenal glands are destroyed by cancer, amyloidosis, antiphospholipid syndrome, adrenomyeloneuropathy, acquired immunodeficiency syndrome (AIDS), infections (e.g., tuberculosis, cytomegaly, fungi), or other identifiable diseases (Box 148-1). In these cases, the typical morphologic changes of the adrenal cortex are atrophy, inflammation, and/or necrosis. In primary adrenal insufficiency, the whole adrenal cortex is involved,

FIGURE 148-1 ■ Cellular mechanisms of glucocorticoid effects (right) and glucocorticoid resistance (left). After passive transport through the cell membrane, glucocorticoids (GC) bind to the intracellular GC receptor alpha (GR α), which is sequestered in the cytoplasm, bound to the heat-shock protein (HSP) complex that comprises chaperone molecules HSP70 and HSP90. Binding of GC to GR α allows formation of a homodimer that is transported into the nucleus. GR-mediated transcription induces inhibitor kappa B alpha (I κ B α), which binds to and inhibits nuclear factor kappa B (NF- κ B). Thus, GC inhibits the NF- κ B-mediated synthesis of proinflammatory cytokines like tumor necrosis factor alpha (TNF- α). Impaired GC sensitivity (GC resistance) includes three major pathways (dotted arrows): (1) decreased cytoplasmatic GC concentrations secondary to increased P-glycoprotein-mediated efflux of GC due to overexpression of the MDR-1 gene; (2) increased expression of a truncated splice variant of the GR that is unable to transactivate GC-sensitive genes (GR β); and (3) activation of proinflammatory mediators via upstream kinases (JNK), which can directly inhibit GR transcription activity. GC, glucocorticoids; GR, glucocorticoid receptor; HSP, heat shock protein; JNK, c-Jun N-terminal kinase; MDR-1, multidrug resistance gene 1.

BOX 148-1 Etiology of Adrenal Insufficiency

PRIMARY ADRENAL INSUFFICIENCY

- Autoimmune adrenalitis (Morbus Addison), often with concomitant endocrinopathies
- Hemorrhage (trauma, anticoagulants)
- Infarction, thrombosis
- Tumors
- Infections (tuberculosis, cytomegaly, fungi, AIDS)
- Amyloidosis, hemochromatosis, sarcoidosis
- Congenital hyper- or hypoplasias
- Congenital ACTH resistance
- Adrenomyeloneuropathy

SECONDARY ADRENAL INSUFFICIENCY (LESIONS OF PITUITARY AND/OR HYPOTHALAMIC REGIONS)

- Tumors
- Hemorrhages, apoplexy
- Infections, inflammations
- Autoimmune lesions
- Trauma, surgery
- Radiation
- Congenital syndromes (e.g., familial CBG deficiency)

resulting in a deficiency of GCs, mineralocorticoids, and adrenal androgens.^{34,35}

Secondary adrenal insufficiency is characterized by adrenal hypofunction due to the lack of pituitary ACTH or hypothalamic CRH. Diseases of the anterior pituitary that can cause secondary adrenal insufficiency include neoplasms (e.g., craniopharyngiomas, adenomas), infarction (e.g., Sheehan's syndrome, trauma), granulomatous disease (e.g., tuberculosis, sarcoidosis), hypophysectomy, and infection.³⁶ Causes also include hypothalamic dysfunction, such as after irradiation or surgical intervention (see Box 148-1). Because aldosterone secretion is more dependent on angiotensin II than on ACTH, aldosterone deficiency is not a problem in secondary adrenal insufficiency. Selective aldosterone deficiency can occur as a result of depressed renin secretion and angiotensin II formation.³⁴ Rarely, patients have an isolated deficiency of CRH,³⁷ and lymphocytic hypophysitis with subsequent adrenal insufficiency has been described in women.³⁸ These disorders may lead to an isolated ACTH deficiency.³⁴

The so-called *tertiary adrenal insufficiency*, which is often summarized together with secondary forms, commonly occurs after withdrawal of exogenous GCs. Many of these patients do well during normal activities but are unable to mount an appropriate GC response to stress. This effect depends on the dose and duration of treatment

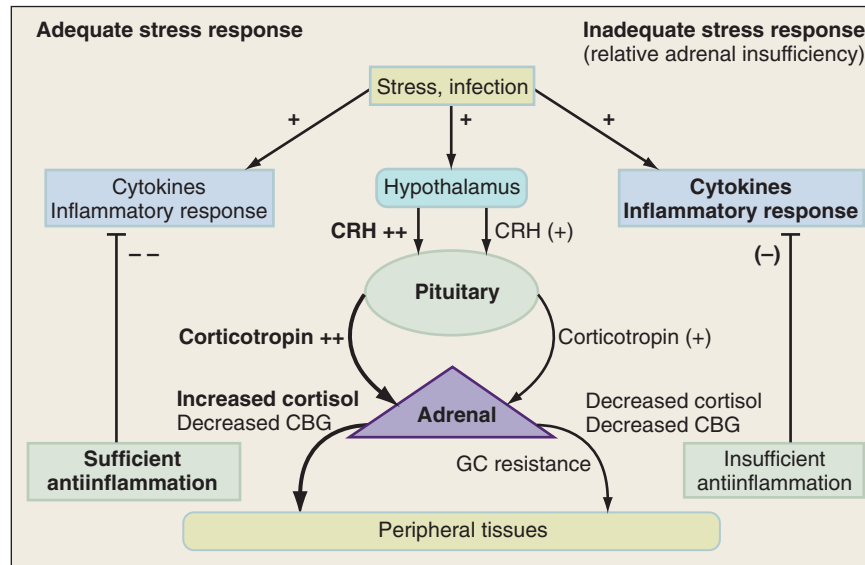

FIGURE 148-2 ■ Concept of relative adrenal insufficiency (RAI). Unlike in an adequate stress response (*left*), RAI may occur when causal or additional factors impair the function of the hypothalamic-pituitary-adrenal (HPA) axis. This may be due to microcirculatory failure, additional drugs like antibiotics, anesthetic drugs, infections, long-term use of steroids, or hemorrhages. Impaired HPA axis function results in an insufficient antiinflammatory response and an increased inflammatory response. Plus (+) denotes activation; minus (–), inhibition. CBG, cortisol-binding globulin; CRH, corticotropin-releasing hormone; GC, glucocorticoids.

and varies greatly from person to person. It should be anticipated in any patient who has been receiving more than 30 mg of hydrocortisone per day (or 7.5 mg of prednisolone or 0.75 mg of dexamethasone per day) for more than 3 weeks.³⁵ If supraphysiologic doses of GCs have been administered to a patient for more than 1 to 2 weeks, the drug should be tapered to allow for adrenal gland recovery. It may take 6 to 12 months for the adrenal glands to recover fully after prolonged use of exogenous GCs.³⁹ Since ACTH is not a major determinant of mineralocorticoid production, the basic deficit in adrenal insufficiency is that of deficient GC production. It is important that neither the dose of applied GCs, nor the time of treatment, nor the basal plasma level of cortisol allows sufficient assessment of the function of the HPA axis. Several drugs have also been described to induce adrenal insufficiency, either by directly affecting adrenocortical steroid release (e.g., fluconazole, etomidate)^{40,41} or by enhanced hepatic metabolism of cortisol (e.g., rifampicin, phenytoin).³⁵

Isolated hypoaldosteronism is very rare and should be suspected in cases of hyperkalemia in the absence of renal insufficiency. The main causes for isolated deficiency of aldosterone secretion are congenital deficiency of aldosterone synthetase, hyporeninemia due to defects in the juxtaglomerular apparatus, or treatment with angiotensin-converting enzyme inhibitors that lead to loss of angiotensin stimulation. Other forms of hypoaldosteronism usually occur in patients with chronic renal disease and/or diabetes mellitus.

■ RELATIVE ADRENAL INSUFFICIENCY

The aforementioned forms of adrenal insufficiency, which lead to an absolute deficiency of steroid production, are rare in critically ill patients (0% to 3%).⁴² To reflect the notion that subnormal adrenal corticosteroid production during acute severe illness can also occur without obvious structural defects in the HPA axis, deficiency syndromes due to a dysregulation have been termed *functional adrenal insufficiency*.⁴³ Functional adrenal insufficiency can develop during the course of critical illness and is usually transient.³⁵ Decreased levels of GCs occur much more often; these levels might be sufficient in normal subjects but are too low for stress situations, owing to higher need, and

are associated with a worse outcome.⁴⁴ This led to the concept of *relative adrenal insufficiency* (RAI). The major cause for RAI is inadequate synthesis of cortisol due to cellular dysfunction. Hence, in contrast to absolute adrenal insufficiency, the morphologic changes in the adrenal glands associated with RAI may be minor, sometimes characterized by cellular hyperplasia within the adrenal cortex. This is often combined with peripheral GC resistance of the target cells, which is caused by inflammatory events and aggravates the clinical course, although the absolute cortisol serum levels might be normal.⁴⁵ In septic shock, RAI may be due to impaired pituitary corticotropin release, attenuated adrenal response to corticotropin, and reduced cortisol synthesis (Fig. 148-2).^{35,46,47} In addition, cortisol transport capacity may be reduced, and response to cortisol may be impaired at the tissue level by cytokines modulating GC receptor affinity to cortisol and/or GREs.^{48,49} In clinical trials, it was demonstrated that prolonged treatment of systemic inflammation in patients with severe acute respiratory distress syndrome (ARDS) with methylprednisolone can improve the decreased GC response by increasing the GC receptor affinity and reducing the NF-κB-mediated DNA binding and transcription of proinflammatory cytokines.²⁹ Thus, if RAI can be identified, treatment with supplemental corticosteroids may be of benefit.³⁵ Prevalence of RAI in the critically ill varies from 0% to 77% with different definitions, cutoff values, study populations, and adrenal function tests^{34,35,46,50,51} and may be as high as 50% to 75% in septic shock.⁵²

■ EVALUATION OF ADRENAL INSUFFICIENCY

In clinical practice, assessment of adrenal function is difficult, especially in critically ill patients, since the diurnal rhythm is disrupted. Values indicating normal adrenocortical function are listed in Box 148-2. Normally, serum cortisol concentrations in the morning (8:00 AM) of less than 3 µg/dL (80 nmol/L) are strongly suggestive of absolute adrenal insufficiency,⁵³ while values below 10 µg/dL (275 nmol/L) make the diagnosis likely. Basal urinary cortisol and 17-hydroxycorticosteroid excretion is low in patients with severe adrenal insufficiency but may be low-normal in patients with partial

BOX 148-2**Values Indicating Normal Adrenocortical Function**

- Plasma cortisol (7:00 to 8:00 AM): 5 to 25 µg/dL (135 to 700 nmol/L)
- Plasma ACTH (7:00 to 8:00 AM): <70 pg/mL
- Urine excretion rate of free cortisol: 20 to 90 µg/d
- Urine excretion rate of 17-hydroxycorticosteroid (17-OHCS): 4 to 10 mg/d

adrenal insufficiency. Generally, baseline urinary measurements are not recommended for the diagnosis of adrenal insufficiency. To differentiate among primary, secondary, and tertiary adrenal insufficiency in cases of low cortisol, it is recommended to measure plasma ACTH concentrations simultaneously. Inappropriately low serum cortisol concentrations in association with increased ACTH concentrations are suggestive of primary adrenal insufficiency, whereas the combination of low cortisol and ACTH concentrations indicates secondary or tertiary disease. This diagnosis, however, should be confirmed by stimulation of the adrenal gland with exogenous ACTH. In secondary or tertiary adrenal insufficiency, the adrenal glands release cortisol, whereas in primary adrenal insufficiency, the adrenal glands are partially or completely destroyed and do not respond to ACTH.

ACTH stimulation tests usually consist of administering 250 µg (40 International Units) of ACTH (so-called high-dose ACTH stimulation test). For long-term stimulation tests, which are preferred for differentiating between secondary and tertiary adrenal insufficiency, 250 µg of ACTH are infused either over 8 hours or over 2 days.⁵⁴ Serum cortisol and 24-hour urinary cortisol and 17-hydroxycorticosteroid (17-OHCS) concentrations are determined before and after the infusion. This test may be helpful in distinguishing primary from secondary/tertiary adrenal insufficiency. In primary adrenal insufficiency, there is a minimal to no response of plasma or urinary cortisol and urinary 17-OHCS. Increases of these values over the 2 to 3 days of the test are indicative of a secondary/tertiary cause of adrenal insufficiency. In normal subjects, the 24-hour urinary 17-OHCS excretion increases 3- to 5-fold above baseline. Serum cortisol concentrations reach 20 µg/dL (550 nmol/L) at 30 to 60 min and exceed 25 µg/dL (690 nmol/L) at 6 to 8 hours post initiation of the infusion. At present, this approach is used frequently because clinical manifestations of adrenal insufficiency combined with basal cortisol levels, short-term ACTH stimulation tests, and CRH tests (see later discussion) usually provide sufficient information.

A short-term stimulation test with 250 µg ACTH, mostly used for patients who are not critically ill, determines basal serum cortisol levels and the induced-response concentration 30 and 60 minutes after intravenous (IV) administration of ACTH. The advantage of the high-dose test is that pharmacologic plasma ACTH concentrations can be achieved by either IV or intramuscular injection.⁵⁵ This dose of ACTH, however, may be too high to identify mild cases of secondary adrenal insufficiency or chronic deficiencies.⁵⁶ Furthermore, it should not be used when acute secondary adrenal insufficiency (e.g., Sheehan's syndrome) is presumed, since it takes several days for the adrenal cortex to atrophy, and it will still be capable of responding to ACTH stimulation normally. In these cases, a low-dose ACTH test or an insulin-induced hypoglycemia may be required to confirm the diagnosis of adrenal insufficiency.^{57,58} A rise in serum cortisol concentration after 30 to 60 minutes to a peak of 18 to 20 µg/dL (500 to 550 nmol/L) or more is considered a normal response to a high-dose ACTH stimulation test and excludes the diagnosis of primary adrenal insufficiency and almost all cases of secondary adrenal insufficiency except those of recent onset.⁵⁹⁻⁶¹

To further differentiate between secondary and tertiary adrenal insufficiency, laboratory investigations may be augmented by a CRH stimulation test. In both conditions, cortisol levels are low at baseline and remain low after CRH. In patients with secondary adrenal insufficiency, there is little or no ACTH response, whereas in patients with

tertiary disease, there is an exaggerated and prolonged response of ACTH to CRH stimulation that is not followed by an appropriate cortisol response.^{62,63} In the past, the HPA axis was also tested by a stimulated hypoglycemia test. After administering 0.1 units of insulin per kilogram body weight, inducing a hypoglycemic state of less than 40 mg/dL serum glucose, an intact HPA axis is associated with a serum cortisol concentration of more than 20 µg/dL. Nowadays, this procedure is considered obsolete because of the high risk of symptomatic hypoglycemia.

In critically ill patients, primary causes of absolute or RAI are multiple and often undetectable if no specific hypothesis exists. Volume-resistant septic shock or any other form of life-threatening hypotension with an increased need for catecholamines indicates the need to evaluate adrenal function. Previously, a serum cortisol value less than 20 µg/dL was suggestive of the diagnosis of adrenal insufficiency.

Several factors complicate investigations of the HPA axis in patients with critical illness. A short-term ACTH stimulation test may be performed in critically ill patients suspected of having adrenal insufficiency. However, in most patients, RAI will be present, especially in patients with sepsis and septic shock. A clear definition of RAI is still missing, and the pathophysiology is rather complex, which makes it difficult to define clear cutoffs for both basal serum cortisol concentrations and incremental increases after short-term ACTH stimulation tests. Proposed cutoff points may depend on different methods used to measure cortisol, with variations when compared to high-performance liquid chromatography (HPLC) as the reference method.⁶⁴ In addition, considering free cortisol or an increase in free cortisol in response to ACTH could increase accuracy of adrenocortical function tests.⁴⁸ Furthermore, extrapolating the diagnosis from reference values obtained from healthy people or patients with HPA disorders may be misleading, since normal or high-normal cortisol concentrations in septic shock may indicate inadequate adrenal response to stress. In a large series of patients, receiver operating characteristic curve (ROC) analysis reached highest sensitivity (68%) and specificity (65%) for a reference value of less than 9 µg/dL (incremental increase) to detect nonresponders.⁵² Basal cortisol of 34 µg/dL and an incremental increase of 9 µg/dL after stimulation were the best cutoff points to discriminate between survivors and nonsurvivors. The higher the basal plasma cortisol and the weaker the cortisol response to corticotropin, the higher was the risk of death. Some investigators have questioned the discriminative power of the incremental increase of cortisol after stimulation in patients with high basal cortisol values, as increases may reflect adrenal reserve more than adrenal function. Hence, RAI was defined based on the hemodynamic response when a randomly measured cortisol was less than 25 µg/dL.⁴⁶

Routine use of the low ACTH stimulation test in critically ill patients cannot be recommended at present, although the low-dose test is preferred in patients with secondary or tertiary adrenal insufficiency.⁶⁵ After stimulation with 250 µg ACTH, circulating corticotropin concentrations are 40 to 200 pg/mL during stress but may be as high as 60,000 pg/mL.³⁵ Stimulation of the adrenal gland with low doses of ACTH (1 µg) was shown to increase sensitivity and specificity to detect adrenal insufficiency in patients with HPA disorders who respond normally to traditional high-dose stimulation.^{35,66-69} The test is performed by measuring serum cortisol concentrations immediately before and 30 minutes after IV injection of ACTH at a dose of 1 µg (160 mIU) per 1.73 m² body surface.³⁴ This dose stimulates maximal adrenocortical secretion up to 30 minutes post injection, and in normal subjects results in a peak plasma ACTH concentration about twice that of insulin-induced hypoglycemia.⁷⁰ A value of 18 µg/dL (500 nmol/L) or more at any time during the test is indicative of normal adrenal function. The advantage of this test is that it can detect partial adrenal insufficiency that may be missed by the standard high-dose test.^{57,58}

Using the 1-µg ACTH stimulation test to identify patients with RAI in septic shock has been proposed, but the 1-µg stimulation test has not been well validated in critically ill patients or patients with septic shock.^{34,35} In addition, studies evaluating low-dose and high-dose

ACTH stimulation tests in septic shock may have been flawed by methodologic problems. At present, using the 1- μ g ACTH stimulation test cannot be recommended routinely until further data from well-designed randomized studies in septic shock patients are available.

The current recommendation is to use a three-level therapeutic guide for evaluating RAI in critically ill patients, especially those with septic shock. Patients with a random basal cortisol below 15 μ g/dL will likely benefit from low-dose corticosteroid therapy, whereas corticosteroid replacement is unlikely to be helpful when basal cortisol is above 34 μ g/dL. When a random basal cortisol value is between 15 and 34 μ g/dL, adrenocortical stimulation with 250 μ g ACTH should discriminate responders (incremental increase ≥ 9 μ g/dL) from nonresponders (< 9 μ g/dL). However, it has been pointed out that no cutoff values are entirely reliable.³⁵

CLINICAL SYMPTOMS

About 25% of patients with adrenal insufficiency present with adrenocortical crisis.³⁴ The symptoms are nonspecific and include sudden dizziness, weakness, dehydration, hypotension, and shock (Box 148-3). In many cases, the clinical picture may be indistinguishable from shock due to loss of intravascular fluid volume. Other features such as anorexia, nausea, vomiting, diarrhea, abdominal pain, and delirium may be present, but they are also common in patients with other acute illness. Hence, these symptoms may not be helpful in establishing the diagnosis of adrenal insufficiency and are often misleading. Hypoglycemia is rare in acute adrenal insufficiency but more common in secondary adrenal insufficiency; it is a common manifestation in children and women with the disorder. For patients in the intensive care unit (ICU), it remains extremely difficult to recognize acute, absolute adrenal insufficiency based on clinical symptoms. However, if the diagnosis is missed, the patient will probably die, so the threshold for laboratory investigations in cases of unexplained catecholamine-resistant hypotension should be low. It is important to be mindful that the onset of an acute adrenocortical crisis is not necessarily the acute beginning of the underlying disease itself. The preceding course is often gradual and may go undetected until an acute illness, stress, trauma, pregnancy, or other conditions precipitate adrenal crisis.^{34,71}

BOX 148-3

Clinical Manifestations of Adrenal Insufficiency

ACUTE ADRENAL INSUFFICIENCY

- Acute apathy
- Nausea, vomiting
- Fever
- Acute dehydration, tachycardia
- Craving for salt
- Hypotension, shock

CHRONIC ADRENAL INSUFFICIENCY

- Weakness, fatigue
- Lack of appetite
- Orthostatic hypotension
- Weight loss, anorexia
- Hyperpigmentation (only in primary Addison's disease due to increased ACTH)
- Vitiligo
- Nonspecific gastrointestinal symptoms (diarrhea, nausea, abdominal pain)
- Nonspecific pain (myalgia, arthralgia, headaches)
- Nonspecific psychological symptoms (depression, lack of concentration, confusion, psychosis)
- Hypoglycemia
- Hyponatremia
- Hyperkalemia
- Acidosis, prerenal azotemia
- Lymphocytosis, eosinophilia

Typical symptoms of primary adrenal insufficiency, such as hyperpigmentation, scanty axillary and pubic hair, hyponatremia, or hyperkalemia may be diagnosed in the acutely ill patient. Adrenal crisis can occur in patients receiving appropriate doses of GCs if their mineralocorticoid requirements are not met.⁷² After spontaneous events leading to primary adrenal insufficiency (e.g., hemorrhage, myocardial infarction, adrenal vein thrombosis), these signs are absent. If an acute adrenal crisis is suspected, a blood sample should be obtained to confirm the diagnosis. The main clinical problem is hypotension and shock due to acute mineralocorticoid deficiency. However, GC deficiency may also contribute to hypotension by decreasing vascular responsiveness to angiotensin II, norepinephrine, and other vasoconstrictive hormones, reducing the synthesis of renin substrate and increasing production and effects of prostacyclin and other vasodilatory hormones.^{73,74} Finally, panhypopituitarism may be associated with symptoms, owing not only to lack of corticotropin but also TSH, gonadotropin, and GH.

In chronic adrenal insufficiency, the major clinical features (see Box 148-3) may be detected but may also be absent if adrenal gland insufficiency develops over a prolonged period of time. There is a stage characterized by normal basal steroid secretion but an inability to respond to stress; hence, the patient may be asymptomatic. In other cases, there may also be signs and symptoms suggestive of other hormone deficiency such as decreased thyroid and gonadal function. Independent of the underlying cause, the most common clinical manifestations are general malaise, fatigue, weakness, anorexia, weight loss, nausea, vomiting, abdominal pain, arthralgia, postural syncope, diarrhea that may alternate with constipation, hypotension, electrolyte abnormalities (hyponatremia, hyperkalemia, metabolic acidosis), decreased axillary and pubic hair, and loss of libido and amenorrhea in women.^{34,71}

In primary adrenal insufficiency, hyperpigmentation and autoimmune manifestations (vitiligo) are typically due to increased ACTH concentrations, whereas these findings are not seen in secondary or tertiary adrenal insufficiency. Another specific symptom of primary adrenal insufficiency is a craving for salt.³⁵ Typical laboratory abnormalities are hyponatremia, hyperkalemia, acidosis, slightly elevated creatinine concentrations, mild normocytic anemia, and, rarely, hypercalcemia.³⁵

In secondary adrenal insufficiency, since production of mineralocorticoids by the zona glomerulosa is generally preserved, dehydration and hyperkalemia are not present, and hypotension is less prominent than in primary disease. Especially in the early stages, the onset of chronic adrenal insufficiency is often insidious, and the diagnosis may be difficult. Some patients initially present with gastrointestinal symptoms such as nausea, vomiting, diarrhea, and abdominal cramps.^{35,75} In other patients, the disease may be misdiagnosed as depression or anorexia nervosa.^{76,77} Hyponatremia and increased intravascular volume may be the result of an "inappropriate" increase in vasopressin secretion. Decreased libido and potency as well as amenorrhea may occur. Hypoglycemia is more common in secondary adrenal insufficiency, possibly due to concomitant GH insufficiency, and in isolated ACTH deficiency. Clinical manifestations of a pituitary or hypothalamic tumor, such as signs and symptoms of deficiency of other anterior pituitary hormones, headache, or visual field defects, may also be present.^{34,71} Finally, in young patients suspected of having adrenal insufficiency, delayed growth and puberty point to the presence of hypothalamic-pituitary disease, as would headaches, visual disturbances, or diabetes insipidus in patients of any age.^{35,36} Laboratory screening in patients with chronic adrenal insufficiency usually reveals hyponatremia, hypoglycemia, lymphocytosis, and eosinophilia.³⁵

THERAPEUTIC APPROACHES

Treatment of adrenal insufficiency involves addressing the precipitating cause (e.g., tumor, infection) and hormone replacement. In acutely ill patients, if the diagnosis of adrenal crisis is suspected but not known, blood should be obtained for measurement of cortisol concentrations,

followed by the administration of 250 µg of ACTH in patients with an unknown history. Replacement therapy should be started immediately while awaiting the results of testing.⁷⁸ Dexamethasone (1 mg every 6 hours) may be given as the initial GC replacement, since it does not cross-react with cortisol in the plasma while adrenal testing is being performed. Patients are usually treated with IV fluids in the form of isotonic saline to restore intravascular volume and replace urinary salt losses. Dextrose infusion may be added to prevent hypoglycemia. Hydrocortisone (100-mg IV bolus or over 30 min, followed by continuous infusion of 10 mg/h, or 50 mg every 4 hours, or 75 to 100 mg every 6 hours, resulting in a total daily dose of 240 to 300 mg hydrocortisone) is frequently given for hormonal replacement.^{34,78} However, equivalent GC doses of methylprednisolone or dexamethasone may also be used. Typically, mineralocorticoid replacement therapy is not required in adrenal crisis as long as the patient is receiving isotonic saline. Prophylactic use of antibiotics is not beneficial, but specific infections should be treated aggressively with appropriate antibiotic therapy.

Once the patient is stable, GCs can be tapered to maintenance doses. Long-term replacement doses consist of hydrocortisone, usually 30 mg/d, with two-thirds (20 mg) given in the morning and one-third (10 mg) given at night, or prednisone, 7.5 mg in a similar regimen (5 and 2.5 mg, respectively). The daily dose may be decreased to 20 or 15 mg of hydrocortisone as long as the patient's well-being and physical strength are not reduced.³⁴ The goal should be to use the lowest dose that relieves the patient's symptoms, in order to prevent weight gain and osteoporosis.^{34,78,79} If the patient continues to experience weakness or other symptoms of GC deficiency, the dose can be increased. Excessive GC therapy should be avoided so as to minimize complications. In addition, mineralocorticoid effect is provided with fludrocortisone (50-100 µg orally daily) to prevent sodium loss, intravascular volume depletion, and hyperkalemia, especially when the dose of hydrocortisone decreases below 100 mg/d. Therapy can be guided by monitoring blood pressure, serum potassium, and plasma renin activity, which should be in the upper normal range.^{34,61} Clinical response, however, is the best indicator of the adequacy of replacement. Excessive mineralocorticoid replacement may cause congestive heart failure, alkalosis, hypokalemia, or hypertension. Patients receiving prednisone or dexamethasone may require higher doses of fludrocortisone to lower their plasma renin activity to the upper normal range, whereas patients receiving hydrocortisone, which has some mineralocorticoid activity, may require lower doses. The mineralocorticoid dose may have to be increased in the summer, particularly if patients are exposed to temperatures above 29°C (85°F). In cases of isolated hypoadosteronism, treatment includes liberal sodium intake and daily administration of fludrocortisone. In patients with secondary adrenal insufficiency due to panhypopituitarism, replacement with other hormones may also be necessary. In women, the adrenal cortex is the primary source of androgen in the form of dehydroepiandrosterone and dehydroepiandrosterone sulfate. Although the physiologic role of these androgens in women has not been fully elucidated, their replacement is being increasingly considered in the treatment of adrenal insufficiency.^{80,81}

Once the patient is stable and on maintenance doses of steroids, ACTH testing can be repeated to document adrenal recovery. Patients with primary adrenal insufficiency require lifelong GC and mineralocorticoid replacement therapy and should carry a card containing information on current therapy, as well as some type of MedicAlert bracelet or necklace with recommendations for treatment in emergency situations. One of the important aspects of the management of chronic primary adrenal insufficiency is patient and family education. Patients should understand the reason for lifelong replacement therapy, the need to increase the dose of GCs during minor or major stress, and how to inject hydrocortisone, methylprednisolone, or dexamethasone in emergencies. Patients should also have supplies of dexamethasone sodium phosphate and should be educated about how and when to administer it. The survival rate for patients with chronic primary adrenal insufficiency has gone from 2 years or less before the availability of steroid replacement to that of the normal population now that GCs are readily available. In acute adrenal insufficiency, prompt

recognition and treatment usually result in a favorable outcome, provided the underlying disease process can be treated.

GLUCOCORTICOID REPLACEMENT IN PATIENTS WITH SEPTIC SHOCK

In patients with sepsis and septic shock, the clinical course is extremely varied. The impact of the primary disease, as well as immunologic factors (including cytokines) associated with sepsis, affect the HPA axis. In contrast to the early phase of septic shock, adrenal cortisol release may recover, thus leading to RAI with absolute steroid levels around or even above normal range.⁸² In refractory septic shock, prevalence of RAI may be as high as 50% to 75%.⁵² Furthermore, dynamic testing is not always available in ICUs, making it difficult for the physician considering hormone replacement therapy, because decisions have to be made within hours in severe forms of septic shock to improve prognosis.

Proposed mechanisms of protection from high-dose GCs include improvement of hemodynamic, metabolic, endocrine, and phagocytic functions, resulting in the maintenance of normal morphologic-functional status of tissues including brain, liver, heart, kidneys, and adrenals.⁸³ In addition, GCs are recognized to inhibit key features of inflammation: endothelial cell activation and damage, capillary leakage, granulocyte activation, adhesion and aggregation, complement activation, and formation and release of eicosanoid metabolites, oxygen radicals, and lysosomal enzymes.⁸⁴⁻⁸⁹

However, in only one long-term, prospective study in humans receiving high doses of methylprednisolone (30 to 60 mg/kg) or dexamethasone (2 to 4 mg/kg), including 179 bacteremic septic shock patients over a period of 8 years, were experimental results confirmed and mortality reduced from 38% to 10%.⁹⁰ Evidence from another study suggested that prolongation of treatment might have been beneficial, since shock reversal and improved survival occurred after a bolus GC application in an early time window but vanished after several days.⁹¹ Two meta-analyses included 9 and 10 randomized trials, respectively, of patients with severe sepsis and septic shock who received up to 42 g of hydrocortisone equivalent or more; both concluded that high doses of corticosteroids were ineffective⁹² or harmful.⁹³ This was confirmed by a large randomized trial in 1987.⁹⁴ High-dose GCs were associated with increased risk of secondary infections, mortality,⁹³ and increased incidence of renal and hepatic dysfunction.⁹⁵ Taken together, these results suggest that high-dose GCs are not effective in septic shock.

Similar to studies of high-dose GC treatment, numerous randomized controlled trials with low-dose corticosteroids in patients with septic shock also confirmed shock reversal and reduction of vasopressor support within a few days after initiation of therapy in most patients.⁹⁶⁻¹⁰¹ In a crossover study, mean arterial pressure and systemic vascular resistance increased during low-dose hydrocortisone treatment, and heart rate, cardiac index, and norepinephrine requirement decreased significantly.¹⁰² All effects were reversible with cessation of hydrocortisone. Some studies indicated that corticosteroid-induced increase of sensitivity to norepinephrine was more pronounced in patients with RAI than in patients without RAI.^{46,101} There are multiple potential mechanisms by which corticosteroids may modulate vascular tone. Considerable evidence confirms that cytokine-induced formation of nitric oxide (NO) plays a central role in vasodilation, catecholamine resistance, maldistribution of blood flow, and mitochondrial and organ dysfunction and that the amount of NO production correlates with shock severity and outcome.^{103,104} In a crossover trial, norepinephrine requirement could be reduced by administering low-dose hydrocortisone in nearly all patients within 1 to 2 days. Hydrocortisone treatment also induced a significant and prolonged decline of nitrite/nitrate levels, which significantly correlated with reduction of norepinephrine requirements during hydrocortisone infusion.¹⁰² Considering the complex genomic and nongenomic actions of corticosteroids described earlier, it is probable that NO is not the only

GCs modulate the stress response in a very complex manner that includes not only antiinflammatory and immunosuppressive actions to protect the host from overwhelming inflammation but also immune-enhancing effects.²⁷ Markers of the inflammatory response, antiinflammatory response, granulocyte, monocyte, endothelial activation, antigen-presenting capacity, and innate immune response were investigated in septic shock patients.¹⁰² Hydrocortisone significantly attenuated inflammatory and antiinflammatory responses as well as granulocyte, monocyte, and endothelial activation. Monocyte HLA-DR expression was depressed, but receptor downregulation was limited and was followed by a rebound increase after drug withdrawal.¹⁰² The immune effects of low-dose hydrocortisone treatment in septic shock may thus be characterized as immunomodulatory rather than immunosuppressive.

Although data on outcomes in septic shock patients after low-dose corticosteroid treatment are limited, up to 300 mg hydrocortisone per day may improve survival. In some trials with low-dose corticosteroids,⁹⁶⁻¹⁰⁰ 28-day all-cause mortality was reduced, whereas in high-dose trials, there was no significant effect. In a multicenter trial in 300 patients with severe volume and catecholamine-refractory septic shock, survival time was significantly increased in patients with RAI but not in responders to ACTH.⁹⁷ Similar results were obtained for ICU and hospital mortality but not for 1-year follow-up. Significant increases of serious adverse events during treatment with low-dose hydrocortisone have not been reported. The incidence of gastrointestinal bleeding, superinfections, or hyperglycemia has not been different in patients treated with corticosteroids or placebo, and wound infections were even less frequent in patients treated with low-dose hydrocortisone.⁹⁷ However, these findings were not confirmed by another large randomized trial, the Corticosteroid Therapy of Septic Shock (CORTICUS) trial,¹⁰⁵ which used different inclusion criteria. Only patients who were successfully resuscitated by volume therapy plus vasopressors were included.¹⁰⁵ These contradictory results led the Surviving Sepsis Campaign to redefine their guidelines in 2012/2013,¹⁰⁶ recommending against the use of low-dose GCs for patients who are responding adequately to volume plus vasopressor therapy—that is, those who are no longer hypotensive. Only in the minority of patients, when a stabilization of blood pressure cannot be obtained by using volume plus vasopressors, continuous, low-dose hydrocortisone might be considered.¹⁰⁶

Treatment with low-dose hydrocortisone may induce an increase of sodium levels within a few days, and hyponatremia with values over 155 mmol/L have been reported during prolonged treatment.¹⁰⁰ Nevertheless, the indication for low-dose corticosteroids should be weighed against possible risks, and treatment should be limited to the duration of volume- and vasopressor-restrictive hypotension.

Dosing of hydrocortisone in septic shock is similar to that in adrenal crisis (100 mg initial bolus, followed by 200–300 mg per day), and the dose should be tapered once the patient stabilizes. Hydrocortisone is the synthetic equivalent to the physiologic final active compound, cortisol, so treatment with hydrocortisone directly replaces cortisol independently from metabolic transformation. In contrast to dexamethasone, hydrocortisone has intrinsic mineralocorticoid activity. A recent randomized trial demonstrated that the addition of oral fludrocortisone to low-dose hydrocortisone has no benefit in septic shock patients.¹⁰⁷ It has not been established whether a weight-adjusted regimen (e.g., 0.18 mg/kg/h)⁵⁶ of continuous hydrocortisone infusion is superior to a fixed regimen; moreover, a comparative study of bolus versus infusion regimens has not been performed so far. Patients should be weaned from low-dose hydrocortisone over several days to avoid hemodynamic and immunologic rebound effects. In patients with septic shock, abrupt cessation of low-dose hydrocortisone was followed by significant reversal of many hemodynamic and immunologic effects observed during corticosteroid therapy, even after a short treatment period of 3 days.¹⁰² Adrenal function tests with 250 µg ACTH can be performed in patients with septic shock; however, at present this approach cannot be recommended to exclude responders or patients with high random cortisol values from low-dose cortico-

steroid therapy.³⁵ When basal serum cortisol concentrations are less than 15 µg/dL in septic shock, low-dose hydrocortisone replacement is recommended; levels of over 34 µg/dL are considered sufficient. Between 15 and 34 µg/dL, an incremental increase of less than 9 µg/dL serum cortisol makes RAI likely, and therapy may be considered according to the clinical state.³⁵ Other recommendations use a randomly assigned cutoff level of below 25 µg/dL serum cortisol.⁴⁶ The routine use of the low ACTH stimulation test (1 µg ACTH) cannot be recommended at present until further data from well-designed randomized studies in septic shock patients are available. Most importantly, it has to be realized that all the aforementioned studies were performed in patients with catecholamine-resistant septic shock. To date, there are no data justifying the use of low-dose steroids in patients with sepsis. Significant effects on outcome have been observed only in patients with systolic blood pressure below 90 mm Hg despite vasopressor therapy.⁹⁷ It is not yet known whether low-dose corticosteroids are also effective in patients with less severe shock. Sufficient data on the dose-response characteristics of GCs in septic patients are still lacking, and the current recommended strategy using 200 to 300 mg hydrocortisone per day is based on empiric recommendations; further investigations are needed.

FURTHER IMPLICATIONS FOR ANESTHESIA AND CRITICAL CARE

Surgical stress increases serum cortisol levels five- to sixfold postoperatively, with return to normal at 24 hours unless stress continues. Patients who have received GCs equivalent to 30 mg/d cortisol for longer than 3 weeks may have impairment in this stress response, and steroid supplementation should be considered. However, short-term treatment of heterogeneous groups of patients with critical illness is controversial, and supraphysiologic doses of GCs are not beneficial and may even be harmful.¹⁰⁸ Hence, outside the situations in which benefit has been proved, supraphysiologic doses of GCs (e.g., 30 mg methylprednisolone per kilogram of body weight per day) in patients with critical illness are not indicated. While early treatment with dexamethasone was suggested to decrease morbidity in bacterial meningitis,^{109,110} a recent meta-analysis was less enthusiastic.¹¹¹ The positive effects of steroid treatment on tissue-specific resistance to GCs have already been described. However, despite the frequent suggestion that unexplained intraoperative hypotension and even death reflect unrecognized hypocortisolism, there is no evidence that primary adrenal insufficiency is a likely explanation for this response.

Patients with known chronic adrenal insufficiency must be advised to double or triple the dose of hydrocortisone temporarily whenever they have any febrile illness or injury.³⁴ In stressful situations or during major surgery, trauma, burns, or medical illness, high doses of GCs up to 10 times the daily production are required to avoid an adrenal crisis, although no data from randomized trials are available. A continuous infusion of 10 mg of hydrocortisone per hour or the equivalent amount of dexamethasone or prednisolone eliminates the possibility of GC deficiency. This dose can be halved on the second postoperative day, and the maintenance dosage can be resumed on the third postoperative day. However, it is important with regard to possible detrimental effects and the possibility of decreased resistance to infections that this treatment should not be used for prolonged periods in the absence of evidence of corticosteroid insufficiency. General perioperative management should include avoidance of etomidate as an anesthetic drug (selection of other drugs and muscle relaxants is not influenced by the presence of treated hypocortisolism); infusion of sodium-containing fluids; minimal doses of any anesthetic drugs to avoid increased sensitivity to drug-induced myocardial depression; invasive monitoring of hemodynamics, glucose, and electrolytes; and decreased initial doses of muscle relaxant while monitoring the effect using a peripheral nerve stimulator. Especially when acute adrenal insufficiency has been detected in a critically ill patient with a previously unknown disorder, thorough diagnostic evaluation is required, even after improvement.

The control of cortisol secretion in response to stress is more complex than originally thought. Interactions between corticotropin-releasing factor (CRF), vasoactive intestinal polypeptide, arginine vasopressin, catecholamines, and other hormones involved in the control of cortisol secretion have been described.¹¹² α_2 -Adrenergic receptor antagonists (e.g., clonidine), which are widely used in ICUs, may suppress the cortisol response to surgical stress. On the other hand, increases in intracranial pressure stimulate cortisol release without increasing ACTH levels, and adrenalectomy, but not adrenal demedullation, increase the permeability of brain tissue to macromolecules.¹¹³ Evidence also suggests that white blood cells may release ACTH-like peptides that can stimulate adrenal gland secretion of cortisol and that primary adrenal insufficiency is associated with increases in serum levels of angiotensin-converting enzyme.¹¹⁴

There are multiple interactions between drugs and the HPA axis that have to be considered if absolute or RAI is suspected. Moreover, in patients with hepatic dysfunction, GC doses should be tapered, especially when using prednisone, since hydroxylation to the active component needs considerable metabolic capacity. Special attention is required in the concomitant use of GCs with other drugs, because of potential interactions and because some drugs may affect the metabolism of steroids, which may lead to a decreased or increased GC effect on their target tissues.^{115,116} GCs decrease blood levels of aspirin, coumarin anticoagulants, isoniazid, insulin, and oral hypoglycemic agents, whereas cyclophosphamide and cyclosporine levels may be increased. Conversely, antacids, carbamazepine, cholestyramine, colestipol, ephedrine, mitotane, phenobarbitone, phenytoin, and rifampicin decrease GC blood concentrations, whereas they are increased by cyclosporine, erythromycin, oral contraceptives, and troleandomycin. Furthermore, the combination of exogenous GC administration and amphotericin B, digitalis glycosides, and potassium-depleting diuretics may induce or worsen hypokalemia, warranting frequent monitoring of potassium levels. Finally, the general risk of immunosuppression by

GCs precludes any use of vaccines from live attenuated viruses to avoid severe generalized infections.^{115,116}

CONCLUSION

Underproduction of adrenal hormones can lead to serious illness. GCs play a critical permissive role in intermediary metabolism, are counter-regulatory in relation to insulin, modulate inflammatory and immune responses, and optimize cardiovascular and CNS function. Therefore, diseases with a primary adrenocortical dysfunction or those leading to secondary adrenal insufficiency may have severe sequelae, which often are life threatening. The concept of RAI in critically ill patients with functional disorders of the HPA axis has gained attention. Especially in patients with sepsis and septic shock, this phenomenon is suspected of having a major impact on the severity of illness and prognosis. Both absolute adrenal insufficiency and RAI should be diagnosed by using adequate laboratory investigations. In most cases, testing the basal level of cortisol, combined with a short-term stimulation test with 250 μ g ACTH, can identify the disease. In patients with critical illnesses, however, it continues to be difficult to diagnose RAI.

In cases of suspected adrenal crisis with severe volume- and catecholamine-resistant shock, immediate replacement therapy is indicated. If the diagnosis is questionable, dexamethasone should be administered to allow an appropriate diagnostic evaluation. Once the diagnosis of adrenal insufficiency is made, hydrocortisone is the preferred therapy, since it provides both gluco- and mineralocorticoid effects. After stabilization, the dose of GCs should be tapered down to a total of 20 to 35 mg hydrocortisone per day or equivalent. Randomized controlled trials of high-dose GCs failed to improve outcome from sepsis and septic shock. However, prolonged treatment of refractory septic shock with low doses of corticosteroids is only considered a therapeutic option if the patient does not respond to volume replacement and vasopressor therapy.

KEY POINTS

1. The definition of adrenal insufficiency is based on the inability of the adrenal gland to produce adrenocortical steroid hormones.
2. Three major regulatory influences affect the hypothalamic-pituitary-adrenal (HPA) axis and lead to secretion of corticotropin (ACTH) as the main stimulatory factor for the adrenal cortex to release its hormonal products: circadian diurnal rhythms, stress, and feedback from free cortisol levels in blood and body fluids.
3. Physical or emotional stress leads to an immediate, significant, and possibly continual increase of ACTH and cortisol excretion. This is typically paralleled by loss of the circadian rhythm. The response to stress is proportional to the intensity of the stimulus.
4. The main cause for *primary adrenal insufficiency* (70% to 80%) is an autoimmune disorder that induces morphologic destruction of more than 90% of the adrenal cortex. The result is a critically decreased synthesis of steroids, with typical clinical manifestations.
5. *Secondary adrenal insufficiency* is characterized by reduced stimulation of the intact adrenal gland due to low ACTH levels (hypothalamic-pituitary insufficiency), which also results in reduced cortisol levels.
6. *Tertiary adrenal insufficiency* is caused by long-term treatment with steroid hormones, which induces feedback inhibition of the HPA axis.
7. The definition of *relative adrenal insufficiency* (RAI) in critically ill patients is based on plasma cortisol levels. The critical threshold is a basal cortisol level of 18 to 25 μ g/mL without preceding stimulation.
8. Clinical manifestations of adrenal insufficiency are usually nonspecific and include weakness, anorexia, orthostatic hypotension, and general gastrointestinal symptoms. Typical signs for primary forms are hyperpigmentation due to increased ACTH levels, vitiligo in cases of autoimmune disorders, and hyperkalemia. Secondary forms cause milder symptoms due to maintained mineralocorticoid effects.
9. Evaluation of adrenal insufficiency generally includes measurement of basal serum cortisol concentrations as well as the incremental increase after stimulation with ACTH. A high-dose test (250 μ g ACTH) is preferred, which uses 30- and 60-minute cortisol levels after stimulation. Long-term tests or low doses (1 μ g ACTH) are only used for special indications. Basal values for serum cortisol of less than 3 μ g/dL indicate severe, absolute hypocortisolism warranting immediate intervention. In critically

KEY POINTS—cont'd

- ill patients, basal cortisol levels of less than 18 to 25 $\mu\text{g/mL}$ have been recommended as an indication for low-dose replacement therapy.
10. Acute adrenal insufficiency (Addisonian crisis) requires immediate intervention. Establishing intravenous access, infusion of saline, monitoring serum glucose, and administering dexamethasone after drawing a blood sample may be lifesaving. ACTH stimulation tests should be used for diagnosis. Once the results after stimulation are known, hydrocortisone therapy is preferred for its mineralocorticoid effects.
 11. Chronic adrenal insufficiency may require long-term replacement therapy with gluco- and mineralocorticoids (for primary forms). Any physical or emotional stress must be considered as possibly harmful, with the need for 3 to 10 times increased doses of glucocorticoids.
 12. In patients with septic shock who are not adequately responding to volume and vasopressor therapy, replacement with low-dose hydrocortisone (200 to 300 mg/d) may be considered, although optimal dosing and timing have yet to be established. A preliminary ACTH test in these patients is no longer recommended.

This review presents the current concepts of pathophysiology, diagnosis, and treatment of corticosteroid insufficiency in acutely ill patients.

This paper is an important publication on the cellular pathways of glucocorticoid response. It demonstrates how steroids inhibit NF- κ B, which represents a key pathway of inflammatory diseases.
- Loriaux DL, Fleseriu M. Relative adrenal insufficiency. *Curr Opin Endocrinol Diabetes Obes* 2009;16:392–400.
This review demonstrates that the phenomenon of relative adrenal insufficiency has a crucial impact on outcome in critically ill patients.
- Keh D, Boehnke T, Weber-Carstens S, Schulz C, Ahlers O, Bercker S, et al. Immunologic and hemodynamic effects of “low-dose” hydrocortisone in septic shock: a double-blind, randomized, placebo-controlled, crossover study. *Am J Respir Crit Care Med* 2003;167:512–520.
- The authors performed a randomized trial in patients with septic shock, using a crossover design that demonstrated that (1) hemodynamic stabilization by low-dose steroids is paralleled by reduced synthesis of endogenous nitric oxide, (2) low-dose hydrocortisone modulates rather than suppresses immunologic functions, and (3) rapid withdrawal of steroids induces rebound phenomena with impairment of the clinical course.*
- Annane D, Sebille V, Charpentier C, Bollaert PE, Francois B, Korach JM, et al. Effect of treatment with low doses of hydrocortisone and fludrocortisone on mortality in patients with septic shock. *JAMA* 2002;288:862–871.
This is the first multicenter clinical trial that was able to demonstrate that low-dose hydrocortisone combined with fludrocortisone reduces mortality in patients with severe volume- and vasopressor-restrictive septic shock.
- Sprung CL, Annane D, Keh D, Moreno R, Singer M, Freivogel K, et al. CORTICUS Study Group. Hydrocortisone therapy for patients with septic shock. *N Engl J Med* 2008;358:111–124.
In contrast to the aforementioned study, this randomized trial did not show any benefit of low-dose hydrocortisone therapy in septic shock; however, these patients were responsive to vasopressor therapy, which underlines the relevance of thorough patient selection.

Thyroid storm and myxedema coma are life-threatening emergencies that represent the extreme ends of the spectrum of thyroid dysfunction in the decompensated patient. Their presentation is usually dramatic and is often precipitated by a nonthyroidal-related illness or event. Recognition of these disorders requires a high degree of clinical suspicion because thyroid function abnormalities, as well as other biochemical parameters, do not differ significantly from uncomplicated thyrotoxicosis and hypothyroidism. As thyroid storm and myxedema coma are clinical diagnoses, measurement of serum thyroid hormones serve as confirmatory tests in the appropriate setting.

In contrast to these dramatic clinical presentations, critical illness also causes multiple nonspecific alterations in thyroid hormone concentrations in patients without intrinsic thyroid dysfunction that relate to the severity of the illness. Since a wide variety of illnesses tend to result in the same changes in serum thyroid hormones, such alterations in thyroid hormone indices have been termed the *sick euthyroid syndrome* or *nonthyroidal illness*. The differentiation between patients with sick euthyroid syndrome and those with intrinsic thyroid disease is a frequent diagnostic challenge in the intensive care unit (ICU).

This chapter will review normal thyroid physiology, changes in thyroid hormone metabolism seen with critical illness, and the evaluation of thyroid function in critically ill patients. Finally, diagnosis and management of sick euthyroid syndrome, thyroid storm, and myxedema coma will be reviewed.

NORMAL THYROID HORMONE ECONOMY

Regulation

Synthesis and secretion of thyroid hormone is under the control of the anterior pituitary hormone thyrotropin (or thyroid-stimulating hormone [TSH]). Consistent with a classic negative feedback system, TSH secretion increases when serum thyroid hormone levels fall and decreases when they rise (Fig. 149-1). TSH secretion is also under the regulation of the hypothalamic hormone thyrotropin-releasing hormone (TRH). The negative feedback of thyroid hormone is targeted mainly at the pituitary level but also likely affects TRH release from the hypothalamus. In addition, input from higher cortical centers can affect hypothalamic TRH secretion.

Under the influence of TSH, the thyroid gland synthesizes and releases thyroid hormone. Thyroxine (T_4 , 65% iodine by weight) is the principal secretory product of the thyroid gland, comprising about 90% of secreted thyroid hormone under normal conditions.¹ Although T_4 may have direct actions in some tissues, it primarily functions as a hormone precursor that is metabolized in peripheral tissues to the transcriptionally active 3,5,3'-triiodothyronine (T_3 , 59% iodine by weight).

Metabolic Pathways

The major pathway of metabolism of T_4 is by sequential monodeiodination.² At least three deiodinases, each with its unique expression in

different organs, catalyze deiodination reactions involved in the metabolism of T_4 . Removal of the 5', or outer ring, iodine by type I iodothyronine 5'-deiodinase (D1) or type II iodothyronine 5'-deiodinase (D2) is the "activating" metabolic pathway leading to the formation of T_3 . Removal of the 5', or inner ring, iodine by type III iodothyronine deiodinase D3 is the "inactivating" pathway producing the metabolically inactive hormone 3,3',5'-triiodothyronine (reverse T_3 , rT_3). D1 is found most abundantly in the liver, kidneys, and thyroid. It is upregulated in hyperthyroidism and downregulated in hypothyroidism. D2 is found primarily in the brain, pituitary, and skeletal muscle and is downregulated in hyperthyroidism and upregulated in hypothyroidism. D3 is expressed primarily in the brain, skin, and placental and chorionic membranes. The actions of D3 also include inactivation of T_3 to form T_2 , another inactive metabolite. Under normal conditions, about 41% of T_4 is converted to T_3 , about 38% is converted to rT_3 , and about 21% is metabolized via other pathways, such as conjugation in the liver and excretion in the bile.^{3,4}

T_3 is the metabolically active thyroid hormone and exerts its actions via binding to chromatin-bound nuclear receptors and regulating gene transcription in responsive tissues.⁵ Important in understanding the alterations in circulating thyroid hormone levels seen in critical illness is the fact that only around 10% of circulating T_3 is secreted directly by the thyroid gland, while more than 80% of T_3 is derived from the conversion of T_4 in peripheral tissues.^{1,2} Thus, factors that affect peripheral T_4 -to- T_3 conversion will have significant effects on circulating T_3 levels. Serum levels of T_3 are approximately 100-fold less than those of T_4 , and like T_4 , T_3 is metabolized by deiodination to form diiodothyronine (T_2) and by conjugation in the liver. The half-lives of circulating T_4 and T_3 are 5 to 8 days and 1.3 to 3 days, respectively.³

Serum Binding Proteins

Both T_4 and T_3 circulate in the serum as hormones bound to several proteins synthesized by the liver.⁴ Thyroid-binding globulin (TBG) is the predominant transport protein and binds to approximately 80% of the circulating serum thyroid hormones. The affinity of T_4 for TBG is about 10-fold greater than that of T_3 and, in part, accounts for increased circulating T_4 levels, compared to T_3 levels. Other serum binding proteins include transthyretin,⁶ which binds about 15% of T_4 but little, if any, T_3 , and albumin, which has a low affinity, but a very large binding capacity, for T_4 and T_3 . Overall, 99.97% of circulating T_4 and 99.7% of circulating T_3 is bound to plasma proteins.

Role of Free Hormone

Essential to an understanding of the regulation of thyroid function and the alterations of circulating thyroid hormones seen in critical illness is the "free hormone" concept, which is that only the unbound hormone has metabolic activity. Under regulation by the pituitary, overall thyroid function is affected when there is any change in free hormone concentration. Changes in either the concentrations of binding proteins or the binding affinity of thyroid hormone to the serum binding proteins have significant effects on total serum hormone levels, owing to the high degree of binding of T_4 and T_3 to these proteins. Despite these changes, this does not necessarily translate into thyroid dysfunction.

FIGURE 149-1 ■ Diagram of the hypothalamic-pituitary-thyroid axis. Inhibitory effect of T_4 and T_3 on TSH secretion is shown by dashed line and minus sign, and stimulatory effects of TRH on TSH secretion and TSH on thyroid secretion are shown by solid lines and plus signs. T_4 and T_3 may also have an inhibitory effect on TRH secretion.

THYROID HORMONE ECONOMY IN CRITICAL ILLNESS

Widespread changes in thyroid hormone economy in critically ill patients occurs as a result of (1) alterations in peripheral metabolism of thyroid hormones, (2) alterations in TSH regulation, and (3) alterations in the binding of thyroid hormone to TBG.

Peripheral Metabolic Pathways

One of the initial alterations in thyroid hormone metabolism in acute illness is the acute inhibition of D1, resulting in the impairment of T_4 -to- T_3 conversion in peripheral tissues.⁷ D1 is inhibited by a wide variety of factors, including acute illness (Box 149-1),² resulting in the acute decrease in T_3 production in critically ill patients. In contrast, inner ring deiodination by D3 may be increased by acute illness, resulting in increased levels of rT_3 .⁸ Additionally, because rT_3 is subsequently deiodinated by D1, degradation of rT_3 decreases, and levels of this inactive hormone rise in proportion to the fall in T_3 levels. Nondeiodinative pathways may play an important role in critical illness as sulfoconjugation and alanine side chain deamination/decarboxylation is increased, resulting in increased levels of T_3 -sulfate and Triac, respectively. Sulfoconjugation has been postulated as the reason why T_3 levels fall rapidly during coronary bypass surgery as T_3 levels rise.⁹ Triac, which binds to the thyroid hormone receptor and has weak thyromimetic activity, increases locally during illness and fasting. An increase in Triac production in the pituitary may be a factor in decreasing TSH levels during illness. Finally, in the critical illness setting, there is impaired transport of T_4 to peripheral tissues, such as the liver and kidney, where much of the circulating T_3 is produced, further

contributing to the decrease in the production of T_3 .^{10,11} Interestingly, increased expression of the thyroid hormone transporters OATP1C1 and MCT8 in animal models¹² and increased expression of MCT8 and MCT1 in the liver and muscle in human studies involving critical illness has been observed.¹³ Thus, the mechanism underlying the decrease in tissue transport in this clinical setting has yet to be elucidated.

Thyrotropin Regulation

Serum TSH levels are usually normal early in acute illness.¹⁴ Decreased TRH secretion due to inhibitory signals from higher cortical centers, impaired TRH metabolism,¹⁵ alteration of pulsatile TSH,¹⁶ and the decrease or absence of a nocturnal TSH surge^{16,17} may all further lower TSH levels. Serum levels of leptin, the ob gene product that has been shown to vary directly with thyroid hormone levels,¹⁸ also falls as illness progresses¹⁹ and hypothalamic TRH secretion falls, which in turn lead to lowered TSH levels.²⁰

The decrease of hypothalamic TRH gene expression in animal models is, however, not associated with increased serum T_4 and T_3 levels.¹² Finally, certain thyroid hormone metabolites that are increased during acute nonthyroidal illness may play a role in the inhibition of TSH and TRH secretion.²¹

Common medications used in the treatment of critically ill patients may also have inhibitory effects on serum TSH levels (Box 149-2). Van

TABLE 149-1 Factors That Alter Binding of T_4 to Thyroid-Binding Globulin

| | INCREASE BINDING | DECREASE BINDING |

den Berghe et al.²² reported that intravenous (IV) administration of dopamine for as short a time as 15 to 21 hours can acutely decrease TSH levels, and its withdrawal results in a 10-fold increase in serum TSH levels. In one study, children who received dopamine infusions during a pediatric ICU admission for meningococcal sepsis had lower TSH levels than those who did not.^{23,24} Increased levels of glucocorticoids, whether from endogenous or exogenous sources, also have direct inhibitory effects on TSH secretion.

Serum Binding Proteins

The affinity of thyroid hormones binding to transport proteins and the concentration of serum binding proteins are altered with acute illness (Table 149-1). Serum levels of transthyretin and albumin decrease, especially during prolonged illness, malnutrition, and in high catabolic states. TBG levels may be increased, as seen with liver dysfunction and human immunodeficiency virus (HIV) infection,²⁵ or decreased, as seen with severe or prolonged illness.⁴ TBG may also be rapidly degraded by protease cleavage during cardiac bypass, thereby partially explaining the rapid fall of serum T_3 levels in patients undergoing cardiac surgery.²⁶

An acquired binding defect of T_4 to TBG is commonly seen in patients with critical illness. This is thought to result from the release of some as yet unidentified factor from injured tissues that has the characteristics of unsaturated nonesterified fatty acids (NEFA),²⁷ which also inhibit T_4 -to- T_3 conversion.²⁸ In systemically ill patients, NEFA levels rise in parallel with the severity of the illness,²⁹ and drugs such as heparin stimulate the generation of NEFA.³⁰ Many drugs including high-dose furosemide, antiseizure medications, and salicylates also alter the binding of T_4 to TBG. The alteration in serum binding proteins in critical illness makes estimating free hormone concentrations difficult (see later).

EVALUATION OF THYROID FUNCTION IN CRITICALLY ILL PATIENTS

Diagnostic Tests

Thyrotropin Assays

Abnormal thyroid function tests have been reported in 20% to 40% of acutely ill patients, more than 80% of whom have no intrinsic thyroid dysfunction after resolution of the illness.³¹⁻³³ In a study of 1580 hospitalized patients, only 24% of patients with suppressed TSH values (TSH < assay limit of detection) and 50% of patients with TSH values over 20 mU/L were found to have thyroid disease.^{31,32} More

important, none of the patients with subnormal but detectable TSH values and only 14% of patients with elevated TSH values less than 20 mU/L were subsequently diagnosed with intrinsic thyroid dysfunction. A review by Kaptein and colleagues suggested that patients with isolated increased TSH concentrations in the setting of chronic cardiac, hepatic, or renal disease usually do not persist or progress to overt hypothyroidism.³⁴

The development of sensitive third-generation TSH assays has led to small improvements in discerning between overt hyperthyroidism and nonthyroidal illness.³¹ Overall, however, while a normal TSH level has a high predictive value of normal thyroid function, an abnormal TSH value alone is not helpful in evaluating thyroid function in critically ill patients.

Serum T_4 and T_3 Concentrations

Measurement of free thyroid hormone concentrations in patients with nonthyroidal illness is fraught with difficulty.³⁵ The gold standard for determination of free hormone levels is equilibrium dialysis. However, this technique is labor intensive and time consuming and is thus rarely used. The most commonly available laboratory tests for thyroid hormone concentrations, free T_4 index, free T_4 , and free T_3 , are measured by analog methods; these methods are estimates of free hormone concentrations and are thus subject to inaccuracies.^{36,37}

The free T_4 index (FT4I) is determined by multiplying the total T_4 concentration by the T_3 or T_4 resin uptake, which is an inverse estimate of serum TBG concentrations.³⁷ Free T_4 levels can also be measured by the analog method, a less expensive alternative to the free T_4 index³⁸; the two tests are likely comparably accurate,³⁹ and in a healthy population, there is a close correlation between the free T_4 index and free T_4 levels. However, in critically ill patients, this association is no longer seen, mainly because of difficulties in estimating TBG binding with resin uptake tests. Despite this, the sensitivity of the free T_4 index in a large study of hospitalized patients was 92.3%, compared to 90.7% for the sensitive TSH test.³¹

Of the serum thyroid function tests, serum T_3 concentrations are affected to the greatest degree by alteration in thyroid hormone economy resulting from acute illness. Therefore, there is no indication for routine measurement of serum T_3 levels in the initial evaluation of thyroid function in critically ill patients. This test should be obtained only if thyrotoxicosis is clinically suspected in the presence of a suppressed sensitive TSH and elevated (or high normal) free T_4 index or free T_4 values. The total T_3 assay is preferable to the free T_3 (analog) assay, owing to the variability among laboratories with the latter test.³⁷

Although some investigators have reported that serum rT_3 levels are a significant prognostic indicator of mortality in the ICU,^{11,40} rT_3 levels are generally unreliable and should not be used to distinguish between intrinsic thyroid dysfunction and nonthyroidal illness.⁴¹

Serum Thyroid Autoantibodies

Autoantibodies to thyroglobulin and thyroid peroxidase (TPO), two intrinsic thyroid proteins, are commonly ordered tests.³⁷ Increased serum titers of either or both of these antibodies indicate the presence of autoimmune thyroid disease, but the presence of thyroid autoantibodies alone does not necessarily indicate thyroid dysfunction, as they are present in up to 26% of the general population.^{42,43} Thyroid autoantibodies do, however, add to the sensitivity of abnormal thyroid-stimulating hormone (TSH) and FT4I values in diagnosing known intrinsic thyroid disease.^{31,32}

Imaging Studies

Imaging studies are rarely essential for the diagnosis of thyroid disorders in critically ill patients. Occasionally, functional analysis of thyroid glands using the radioisotope iodine-123 (¹²³I) may be useful in patients with suspected thyrotoxicosis and equivocal laboratory tests. However, these studies are labor intensive, and managing the underlying acute illness often overshadows the benefits of obtaining these studies. Anatomic studies such as ultrasound, isotopic imaging,

FIGURE 149-2 ■ Alterations in thyroid hormone concentrations with critical illness. Schematic representation of the continuum of changes in serum thyroid hormone concentrations in patients with nonthyroidal illness. Alterations become more pronounced with increasing severity of illness and return to normal range as illness subsides and patient recovers. A rapidly rising mortality accompanies the fall in total and free T_4 concentrations. rT_3 , reverse triiodothyronine (3,3',5'-triiodothyronine); T_3 , 3,5,3'-triiodothyronine; TSH, thyroid-stimulating hormone (thyrotropin). (From Farwell AF. Sick euthyroid syndrome in the intensive care unit. In: Irwin RS, Rippe JM, editors. Intensive care medicine. 5th ed. Philadelphia: Lippincott Williams & Wilkins; 2003.)

computed tomography (CT), and magnetic resonance imaging (MRI) are useful in the evaluation of thyroid nodules and goiter, but these conditions are rarely the cause of acute illness; as such, these studies are not usually helpful in critically ill patients.

Diagnosis

Routine screening of an ICU population for the presence of thyroid dysfunction is not recommended because of the high prevalence of abnormal thyroid function tests and low prevalence of true thyroid dysfunction. When thyroid function tests are ordered in hospitalized patients, they should only be done if there is a high clinical index of suspicion for thyroid dysfunction. Whenever possible, it is best to defer evaluation of the thyroid-pituitary axis until the patients have recovered from the acute illness.⁴⁴ Because every test of thyroid hormone function can be altered in critically ill patients, no single test can definitively rule in or rule out the presence of intrinsic thyroid dysfunction.

If there is a high clinical suspicion for intrinsic thyroid dysfunction in critically ill patients, reasonable initial tests should include either free T_4 index or free T_4 and TSH measurements. Assessment of these values in the context of the duration, severity, and stage of illness will allow the correct diagnosis in most patients. For example, a mildly elevated TSH coupled with a low free T_4 index or free T_4 is more likely to indicate primary hypothyroidism early in an acute illness, as opposed to the same values obtained during the recovery phase of the illness. Similarly, the combination of an elevated TSH and low-normal free T_4 index or free T_4 is more likely to indicate thyroid dysfunction in hypothermic, bradycardic patients than the tachycardic, normothermic individuals. If both the free T_4 index or free T_4 and TSH are normal, thyroid dysfunction is effectively eliminated as a significant contributing factor. If the diagnosis is still unclear, measurement of thyroid antibodies is helpful as a marker of intrinsic thyroid disease and increases the sensitivity of both the free T_4 index or free T_4 and the TSH. Only in the case of a suppressed TSH and a mid- to high-normal free T_4 index or free T_4 are measurements of serum T_3 levels indicated.

■ SICK EUTHYROID SYNDROME

As discussed earlier, critical illness causes multiple nonspecific alterations in thyroid hormone concentrations in patients without intrinsic thyroid dysfunction that relate to the severity of the illness.^{21,45,46}

One theory postulates that sick euthyroid syndrome may be a compensatory mechanism in response to the oxidative stress of acute illness.⁴⁷ Whatever the underlying cause, these alterations in thyroid hormone parameters represent a continuum of changes that depends on the severity of the illness and can be categorized into several distinct stages (Fig. 149-2).²¹ The wide spectrum of changes observed often results from the differing points in the course of the illness when the thyroid function tests were obtained. Importantly, these changes are rarely isolated and are often associated with alterations of other endocrine systems, such as decreases in serum gonadotropin and sex hormone concentrations⁴⁸ and increases in serum ACTH and cortisol levels.⁴⁹ Thus, the sick euthyroid syndrome should not be viewed as an isolated pathologic event but as part of a coordinated systemic reaction to illness involving both the immune and endocrine systems.

The effect of nonthyroidal illness has been studied in several acute and chronic diseases. Some investigators have postulated an association between hypothyroidism and chronic kidney disease, although the thyroid function abnormalities in this patient population with a chronic illness may represent a component of nonthyroidal illness.⁵⁰ Others have reported that the presence of nonthyroidal illness portends worsened overall prognosis in patients with coexisting end stage renal disease,⁵¹ cardiorenal syndrome,⁵² and enterocutaneous fistulas⁵³ and in burn patients.⁴⁰ There is limited literature regarding nonthyroidal illness in children hospitalized in the ICU.⁵⁴

Low T_3 State

Common to all of the abnormalities in thyroid hormone concentrations seen in critically ill patients is a substantial depression of serum T_3 levels, which can occur as early as 24 hours after the onset of illness. Over half of patients admitted to the medical service will demonstrate depressed serum T_3 concentrations.^{31,32} As noted above, there are multiple pathways that contribute to the development of the low T_3 state in critical illness, including decrease in peripheral T_4 -to- T_3 conversion through inhibition of type 1 deiodinase, increase in T_3 -to- T_2 conversion through increased type 3 deiodinase expression,⁵⁵ increase in T_3 sulfation, and increase in Triac formation. This results in marked reduction of T_3 production and rT_3 degradation,⁵⁶ thereby leading to reciprocal changes in serum T_3 and serum rT_3 concentrations. The low T_3 state has been described as a predictor of both all-cause and cardiac mortalities in critical care patients with

acute decompensated heart failure.⁵⁷ Low T_3 levels are also found in peripheral tissues.¹¹ Thyroid hormone receptor expression is also decreased in acute nonthyroidal illness,⁵⁸ possibly in response to the decrease in tissue T_3 levels.

High T_4 State

Serum T_4 levels may be elevated early in acute illness due to either the acute inhibition of type 1 deiodinase or increased TBG levels. This is seen most often in the elderly and in patients with psychiatric disorders. As the duration of illness increases, nondeiodinative pathways of T_4 degradation increase serum T_4 levels to the normal range.³²

Low T_4 State

As the severity and duration of the illness increase, serum total T_4 levels decrease into the subnormal range. Contributors to this decrease in serum T_4 levels are (1) a decrease in the binding of T_4 to serum carrier proteins, (2) a decrease in serum TSH levels, leading to decreased thyroidal production of T_4 , and (3) an increase in nondeiodinative pathways of T_4 metabolism. The decline in serum T_4 levels correlates with prognosis in the ICU, with mortality increasing as serum T_4 levels drop below 4 $\mu\text{g}/\text{dL}$ and approaching 80% in patients with serum T_4 levels below 2 $\mu\text{g}/\text{dL}$.⁵⁹⁻⁶¹ Despite marked decreases in serum total T_4 and T_3 levels in critically ill patients, free hormone levels have been reported to be normal or even elevated,^{35,36} providing a possible explanation for why most patients appear eumetabolic despite thyroid hormone levels in the hypothyroid range. Thus, the low T_4 state is unlikely to be a result of a hormone-deficient state and is probably more of a marker of multisystem failure in these critically ill patients.

Recovery State

As acute illness resolves, so do the alterations in thyroid hormone concentrations.⁶² This stage may be prolonged and is characterized by modest increases in serum TSH levels.⁶³ Full recovery with restoration of thyroid hormone levels to the normal range may require several weeks⁶⁴ or months after hospital discharge.³¹ One study reported that 35 of 40 patients with nonthyroidal illness after coronary artery bypass grafting were able to regain normal thyroid function 6 months after surgery.⁶⁵

Treatment of Sick Euthyroid Syndrome

The question of whether the sick euthyroid syndrome in critically ill patients represents pathologic alterations in thyroid function that negatively impact these patients or simply reflects multisystem failure (i.e., respiratory, cardiac, renal, hepatic failure) that occurs in critically ill patients is still debatable.^{52,53,66-69} However, in most studies, thyroid hormone replacement therapy has been shown to not be beneficial (Box 149-3),^{68,69} including in pediatric patients.⁷⁰

Initial evidence suggested a beneficial effect of liothyronine ($L-T_3$) on increasing organs available for harvest from brain-dead patients,⁷¹ such that $L-T_3$ was included in hormonal preservation of organs prior to transplant.⁷² However, a subsequent meta-analysis, including prospective studies, failed to confirm any beneficial effect.⁷³ While $L-T_3$ appears to slightly improve hemodynamic and neurohumoral parameters in patients with dilated cardiomyopathy⁷⁴ and impaired myocardial function,⁷⁵ these benefits may represent a pharmacologic effect of T_3 rather than a physiologic replacement hormonal effect. Further, the studies involving patients with congestive heart failure are more remarkable for a lack of deleterious effect of $L-T_3$ treatment than for any sustained clinical benefit; future studies are warranted in this patient population.

Therapies other than thyroid hormone replacement have been shown to be beneficial in treating the sick euthyroid syndrome. One randomized multicenter clinical trial reported that the use of

BOX 149-3

Summary of Clinical Trials on the Effects of Treatment of Sick Euthyroid Syndrome with Thyroid Hormone*

STARVATION/UNDERNUTRITION

- $L-T_3$ treatment results in increased protein breakdown and increased nitrogen excretion in fasting normal and obese patients.

GENERAL ICU PATIENTS

- No benefit of $L-T_4$ on general medical patients, patients with acute renal failure, or renal transplant
- No benefit of $L-T_3$ on burn patients

PREMATURE INFANTS

- No benefit of $L-T_4$ on developmental indices of premature infants at 26-28 weeks' gestation
- Possible beneficial effect of $L-T_4$ on infants of at 25-26 weeks' gestation but possible deleterious effects on infants of 27-30 weeks' gestation
- No benefit of $L-T_3$
- Meta-analysis shows no significant effects of thyroid hormone treatment on premature infants.

CARDIAC SURGERY PATIENTS

- Small studies suggest improved hemodynamic parameters with $L-T_3$.
- Large trials show no benefit of $L-T_3$ noted in patients undergoing cardiac bypass.
- Possible improvement in hemodynamic parameters and hospital stay with $L-T_3$ in children undergoing cardiac surgery

CARDIAC DONORS

- Variable results (helpful to no benefit) on the effects of $L-T_3$ in preserving function of normal hearts in brain-dead cardiac donors prior to transplantation
- Possible benefits of $L-T_3$ in improving function of impaired hearts prior to transplant, potentially increasing the pool of organs available for transplantation
- Consensus conferences recommend the use of $L-T_3$ as part of the hormonal resuscitation in donors whose cardiac ejection fraction is <45%.

CONGESTIVE HEART FAILURE

- Small uncontrolled study suggested short-term $L-T_4$ therapy increased cardiac output and functional capacity and decreased systemic vascular resistance.
- Improved hemodynamic parameters and neurohumoral profiles with short-term intravenous $L-T_3$ infusion, possibly requiring supraphysiologic concentrations

*Refer to Reference 69 for detailed citations.

N -acetylcysteine (NAC) was able to prevent serum thyroid function derangements, consistent with nonthyroidal illness among patients following an acute myocardial infarction.⁷⁶ The findings suggest that NAC, a potent intracellular antioxidant, is able to reduce oxidative stress, presumed as a causative factor of nonthyroidal illness.⁷⁷ Changes in thyroid hormone parameters occurring postoperatively have been prevented by early institution of nutritional support.⁷⁸ Finally, some investigators have suggested that patients with prolonged critical illness may represent a different disease entity than those with acute disease,^{79,80} and treatment with hypothalamic releasing factors should be tested in future trials.⁷⁹ In summary, in the absence of any clinical evidence of hypothyroidism, there does not appear to be any compelling evidence for the use of thyroid hormone therapy in patients with decreased thyroid hormone parameters due to the sick euthyroid syndrome.⁸¹

THYROID STORM

Thyroid storm is an acute, life-threatening complication of hyperthyroidism and represents the extreme manifestation of the disease.⁸²⁻⁸⁴ Historically, thyroid storm was associated with surgery for hyperthyroidism and approached an incidence of 10% in some series, depending upon the diagnostic criteria employed. Currently, because of better

recognition of the disease and improved perioperative management, thyroid storm is rare, accounting for less than 2% of all hospital admissions related to thyrotoxicosis.⁸⁵ Most often, thyroid storm is precipitated by an intercurrent medical problem in untreated or partially treated hyperthyroid patients.⁸²⁻⁸⁴ The diagnosis of thyroid storm is a clinical one; there are no distinctive laboratory features, and thyroid hormone concentrations are similar to those observed in uncomplicated thyrotoxicosis. Although the cause of rapid clinical decompensation is unknown, a sudden inhibition of thyroid hormone binding to plasma proteins by the precipitating factor, causing a rise in free hormone concentrations in the already elevated free hormone pool, may play a role in the pathogenesis of thyroid storm.⁸⁶

Clinical Manifestations

Thyroid storm is primarily a clinical diagnosis; as such, the varying incidence of this disorder in patient series likely results from the strictness of the diagnostic criteria. Clinical features are similar to those of thyrotoxicosis but more exaggerated (Box 149-4). Cardinal features of thyroid storm include fever (temperature usually $>38.5^{\circ}\text{C}$), tachycardia out of proportion to the fever, and mental status changes.⁸⁷ Tachyarrhythmias, especially atrial fibrillation in the elderly, are common. Nausea, vomiting, diarrhea, agitation, and delirium are frequent presentations. Vascular collapse and shock due to dehydration and cardiac decompensation are poor prognostic signs, as is the presence of jaundice.⁸⁸ Multiorgan failure has been reported.⁸⁹ Coma and death may ensue in up to 20% of patients, frequently due to cardiac arrhythmias, congestive heart failure, hyperthermia, or the precipitating illness.⁹⁰ Involvement of the central nervous system may portend a worsened prognosis.^{91,92}

Most patients display the classic signs of Graves' disease, the most common cause of thyrotoxicosis, with ophthalmopathy and a diffusely enlarged goiter as the usual manifestations.⁸³ Thyroid storm has also been associated with toxic nodular goiters. In the elderly, atypical signs and symptoms may include severe myopathy, profound weight loss, apathy, and a minimally enlarged goiter.⁹³

Precipitating Factors

In the past, thyroid storm was frequently associated with surgery for hyperthyroidism (Box 149-5), with symptoms beginning a few hours after thyroidectomy in patients prepared for surgery with potassium iodide alone. Most of these cases occurred in patients who were not appropriately prepared for surgery by current standards. Certain clinical and socioeconomic factors have also been suggested to be associated with complicated hyperthyroidism, including lack of insurance, age younger than 30 or older than 50, and serum T_4 concentrations greater than twice the upper limit of normal.⁹⁴ Because of better recognition of the disease, preoperative treatment with thionamides to deplete the gland of thyroid hormone prior to surgery, and improved perioperative management with β -blockade, thyroid storm now is rarely a postoperative complication of thyroid surgery.

Currently, thyroid storm appears most commonly following infection, causing the thyrotoxic state to decompensate.⁸³ Pneumonia, upper respiratory tract infections, and enteric infections are common precipitating infections. Other precipitating factors include stress, trauma, nonthyroidal surgery, diabetic ketoacidosis, labor, heart disease, and iodinated contrast studies in unrecognized or partially treated hyperthyroid patients.⁹⁵⁻⁹⁹ Iatrogenic thyroid storm has been reported due to thyroid hormone overdose.^{100,101} Thyroid storm associated with gestational trophoblastic disease and TSH-secreting pituitary adenoma are uncommon.^{102,103} Thyroid storm occurring after ^{131}I therapy is extremely rare.¹⁰⁴⁻¹⁰⁷ When reported, radioiodine-induced thyroid storm usually occurs if there was no pretreatment with antithyroid drugs.¹⁰⁴ Sorafenib, a tyrosine kinase inhibitor used for the treatment of renal cell carcinoma, is known to be associated with thyroid dysfunction and has been described to precipitate thyroid storm.¹⁰⁸

Diagnosis

As mentioned earlier, the diagnosis of thyroid storm is a clinical one. The Burch-Wartofsky⁸² and Akamizu¹⁰⁹ scoring systems may be helpful in distinguishing the likelihood of thyroid storm in patients presenting with hyperthyroid symptoms. These scoring systems utilize criteria that include temperature, central nervous system effects, gastrointestinal effects, cardiovascular effects, and precipitant history to assist in the diagnosis.

There are no distinct laboratory abnormalities apart from elevated thyroid hormone concentrations, which are similar to those found in uncomplicated thyrotoxicosis. Serum T_3 concentrations are often elevated to a greater degree than serum T_4 concentrations, owing to the preferential secretion of T_3 in the hyperthyroid gland.⁸³ There is little correlation between the degree of elevation of thyroid hormones and the presentation of thyroid storm. Serum TSH concentrations are typically undetectable; however, because of the influence of nonthyroidal illness on TSH secretion (see earlier), a low TSH by itself is insufficient to make a diagnosis of thyroid storm. Serum T_4 and T_3 concentrations in the normal range, regardless of the TSH concentration, effectively eliminate thyroid storm as a tenable diagnosis.

Abnormal liver function tests are common. Hypocalcemia may be observed secondary to increased osteoclast-mediated bone resorption in the hyperthyroid patient. Hematocrit concentrations may be elevated due to volume contraction, and leukocytosis is common even in the absence of infection.

The differential diagnosis of thyroid storm includes sepsis, neuroleptic malignant syndrome, malignant hyperthermia, and acute mania with lethal catatonia, all of which can precipitate thyroid storm in the appropriate setting. Clues to the diagnosis of thyroid storm are a

history of thyroid disease, history of iodine ingestion, and the presence of a goiter or stigmata of Graves' disease. The physician must have a high clinical index of suspicion for thyroid storm, as therapy must be instituted before the availability of thyroid function test results in most cases.

Treatment

It should be emphasized that a thyroid storm is an important medical emergency that must be treated in an ICU.⁸²⁻⁸⁴ Therapy can be divided into two major categories (Box 149-6): (1) *thyroid-directed treatment* aimed at decreasing thyroid hormone production, conversion, and secretion and blocking the peripheral manifestations of thyroid hormone and (2) *supportive treatment* aimed at controlling the fever, stabilizing the cardiovascular system, and managing the precipitating cause.

Thyroid-Directed Treatment

Prompt inhibition of thyroid hormone synthesis and secretion is essential. Antithyroid drugs are given in large doses to both inhibit

synthesis of thyroid hormones and block the uptake of iodine. Propylthiouracil (PTU) is preferred over methimazole, given its greater efficacy when used in large doses, in reducing T_3 levels during severe hyperthyroidism (by inhibition of type 1 deiodinase), and impairing peripheral conversion of T_4 to T_3 .¹¹⁰ However, since other more powerful inhibitors of type 1 deiodinase are usually part of the therapeutic regimen in thyroid storm, the main beneficial effects of PTU are its inhibition of iodide uptake and hormone synthesis. PTU and methimazole can be administered by nasogastric tube or rectally, if necessary.¹¹¹ Neither of these preparations is available for parenteral administration, although a protocol has been reported for the reconstitution of methimazole to be given IV.¹¹²

Iodides, the most effective drugs to block release of thyroid hormone from the thyroid gland, should be used only after antithyroid drugs have been administered. Monotherapy with iodides will actually increase the synthesis of new thyroid hormones and markedly worsen the hyperthyroidism when the gland escapes from the initial iodide-induced blockade of hormone secretion (the acute Wolff-Chaikoff effect).¹¹³ Previously, the iodide preparation of choice was the radiographic contrast dye, iopanoic acid (Telepaque), because of its high iodine content (0.6 mg iodine/g dose) and the ability for the drug to directly inhibit type 1 deiodinase and thus block T_4 -to- T_3 conversion.² However, this drug is largely unavailable worldwide. Lugol's solution and saturated solution of potassium iodide (SSKI) are currently the main sources of therapeutic iodides.^{114,115} It is important to realize that use of iodides precludes the use of radioactive iodine as a definitive therapy for hyperthyroidism for several months. Lithium has also been reported to be effective in inhibiting thyroid hormone release to a similar degree as iodides.¹¹⁶

High-dose dexamethasone is recommended as supportive therapy, both as an inhibitor of T_4 -to- T_3 conversion and as management of possible coexistent adrenal insufficiency. β -adrenergic blockers, specifically propranolol, are also weak inhibitors of T_4 -to- T_3 conversion, although their main beneficial effect is on heart rate control.¹¹⁷ Orally administered ion-exchange resin (colestipol or cholestyramine) can trap hormone in the intestine and prevent recirculation.^{118,119} Plasmapheresis, peritoneal dialysis, and charcoal hemoperfusion have also been used in severe cases.¹²⁰

Supportive Treatment

Simultaneously with antithyroid-directed therapy, treatments aimed at cooling the patient down to a reasonable temperature and providing hemodynamic support should be instituted. IV fluids, antipyretics, and cooling blankets are all effective. β -adrenergic blockers such as propranolol (oral or IV) and esmolol (IV) are given for heart rate control. Calcium channel blockers may be used to control tachyarrhythmias. Anxiolytics are frequently helpful once the patient's mental status improves. Finally, treatment of the underlying precipitating illness is essential to survival in thyroid storm.

Long-Term Therapy

Once the acute phase of thyroid storm is controlled, antithyroid drug therapy should be continued until euthyroidism is achieved, while the adjunctive therapy can be discontinued. Definitive therapeutic options for hyperthyroidism include radioactive iodine (after a few months to allow excretion of the excess iodides used during acute management of thyroid storm) and surgery.¹²¹⁻¹²³ Long-term (1 to 2 years) treatment with antithyroid drugs in the hopes of achieving a remission is an option for patients with Graves' disease,¹²⁴ although this is best achieved using methimazole because of the concern about rare complications of severe liver injury with PTU.¹²⁵

MYXEDEMA COMA

Myxedema coma is a rare syndrome that represents the extreme expression of severe long-standing hypothyroidism.^{84,126,127} It is a medical emergency, and even with early diagnosis and treatment, the

BOX 149-6 Treatment of Thyroid Storm

THYROID-DIRECTED THERAPY

Direct

Inhibition of Thyroid Hormone Synthesis

Propylthiouracil: 800 mg PO/PR first dose, then 200 to 300 mg PO/PR q 8 h, *or*
Methimazole: 80 mg PO/PR first dose, then 40 to 80 mg PO/PR q 12 h

Block Release of Thyroid Hormones from the Gland

Telepaque (iopanoic acid): 1 g PO once daily (if available), *or*
SSKI: 5 drops PO q 8 h, *or*
Lugol's solution: 10 drops PO q 8 h, *or*
Lithium: 800-1200 mg PO once daily; achieve serum lithium levels 0.5 to 1.5 mEq/L

Adjunctive

Block T_4 -to- T_3 Conversion

Telepaque (iopanoic acid)
Corticosteroids: dexamethasone, 1 to 2 mg PO/IV q 6 h
Propylthiouracil
Most β -blockers: propranolol, 40 to 80 mg PO q 6 h

Remove Thyroid Hormones from Circulation

Cholestyramine: 4 g PO q 6 h, *or*
Colestipol: 20 to 30 mg PO once daily, *or*
Plasmapheresis, *or*
Peritoneal dialysis

Coarse, dry skin
Myxedema facies
Hypoglycemia
Atonic gastrointestinal tract
Atonic bladder
Pleural, pericardial, and peritoneal effusions

mortality can be as high as 40%.¹⁰¹ The name is somewhat of a misnomer, as actual coma is rare.¹²⁶ The syndrome includes decompensated hypothyroidism, central nervous system impairment, and cardiovascular compromise. Myxedema coma occurs most often in the elderly and during the cold months; in one series in India, 15 of 23 cases of myxedema coma were admitted in the winter.¹²⁸ As with thyroid storm, myxedema coma is usually caused by a precipitating event in untreated or partially treated hypothyroid patients.

Clinical Manifestations

The cardinal features of myxedema coma are (1) hypothermia, which can be profound, (2) altered mental status, (3) cardiovascular depression, and (4) a precipitating cause(s) (Box 149-7). Severely hypothyroid patients essentially become poikilothermic due to disordered thermoregulation. This is the reason many cases occur in the winter months. Body temperatures as low as 23.3°C have been reported; thus, rectal temperatures are essential in making the diagnosis. Excessive lethargy and sleepiness may have been present for weeks to months, often interfering with meals, and patients may even present obtunded.¹²⁹ Decreased consciousness has been found to be an important adverse prognostic indicator for mortality.¹³⁰ Rarely, psychosis and delirium have been reported. Bradycardia and hypotension may be profound, and the respiratory rate is often depressed. Since intrinsic hypothyroidism by itself is insufficient to produce the clinical syndrome of myxedema coma, a precipitating cause must be assumed to be present.¹²⁶

In addition to the noted features, most patients have the physical features of severe hypothyroidism,¹²⁷ including macroglossia, delayed reflexes, dry, rough skin and myxedematous facies, which results from periorbital edema, pallor, hypercarotinemias, and patchy hair loss. Hypotonia of the gastrointestinal tract is common and often so severe as to suggest an obstructive lesion.¹³¹ Urinary retention due to a hypotonic bladder is related but less frequent. Pleural, pericardial, and peritoneal effusions; cardiac tamponade¹³²; and heart failure¹³³ may be present. Severe airway obstruction has been reported.¹³⁴

Precipitating Factors

As mentioned, cold stress is a common precipitant to myxedema coma (Box 149-8). Other common precipitating factors include pulmonary and urinary tract infections, cerebrovascular accidents, trauma, surgery, congestive heart failure, and intravascular volume loss from acute or chronic gastrointestinal bleeding or overuse of diuretics.^{84,126,127} The clinical course of lethargy proceeding to stupor and then coma is often hastened by drugs, especially sedatives, narcotics, antidepressants, and tranquilizers.¹³⁵ Amiodarone, due to its high iodine content, has been reported to induce both thyroid storm¹³⁶ and myxedema coma.¹³⁷ Similar to the association of tyrosine kinase inhibitors and thyroid storm, agents such as sunitinib have also been reported to induce severe hypothyroidism.¹³⁸ Many cases of myxedema coma have occurred in undiagnosed hypothyroid patients who present for other medical problems.¹³⁹

Diagnosis

Like the diagnosis of thyroid storm, myxedema coma is a clinical diagnosis and, similar to thyroid storm, a scoring system by Wartofsky and colleagues has been proposed.¹⁴⁰ Elderly patients may present with particularly subtle findings.¹⁴¹ Even though rare, the diagnosis of myxedema coma should be considered in hypothermic, obtunded patients. Medical histories of these patients, including a prior history of hypothyroidism, may only be able to be confirmed from other sources. Friends, relatives, and acquaintances might have noted increasing lethargy, complaints of cold intolerance, and changes in voice. Clues to the diagnosis include an outdated container of L-T₄ (levothyroxine) discovered with the patient's belongings, which suggests that the patient has been noncompliant in taking thyroid hormone replacement medication. The medical record may also indicate prescribed thyroid hormone use, previous referral to treatment with radioactive iodine, or a history of thyroidectomy. Finally, the physical exam finding of a thyroidectomy scar should raise suspicion as to the diagnosis.

Because more than 95% of cases of myxedema coma are due to primary hypothyroidism,^{84,126,127} the laboratory findings include an elevated serum TSH and low or undetectable total and free serum T₄ concentrations. These thyroid hormone abnormalities are similar to those in uncomplicated overt hypothyroidism. In patients with central hypothyroidism, the diagnosis of myxedema coma may be very difficult, as serum TSH concentrations will be normal or low. However, other symptoms of pituitary dysfunction are usually present in these rare patients.

Dilutional hyponatremia is common and may be severe. Elevated creatine kinase concentrations, sometimes markedly so, are encountered frequently and may misdirect the clinical picture toward cardiac ischemia.^{142,143} However, the MB fraction in most of these cases is normal, and an electrocardiogram (ECG) often demonstrates low voltage and loss of T waves that is characteristic of severe hypothyroidism. Elevated lactate dehydrogenase (LDH) concentrations, acidosis, and anemia are common findings. Lumbar puncture reveals increased opening pressure and high protein content in the cerebrospinal fluid.

Few of the signs and symptoms discussed are unique to myxedema coma. Protein-calorie malnutrition, sepsis, hypoglycemia, and exposure to certain drugs and toxins, as well as cold exposure can cause severe hypothermia. Hypotension and hypoventilation, other cardinal features of myxedema coma, occur in other disease states. Furthermore, low thyroid hormone concentrations may be seen in critically ill patients with nonthyroidal illness (see earlier). As with thyroid storm,

BOX 149-9 Treatment of Myxedema Coma**SUPPORTIVE**

Assisted ventilation
 Hemodynamic support

 Intravenous glucose for hypoglycemia
 Water restriction or hypertonic saline for severe hyponatremia
 Hydrocortisone IV (100 mg q 8 h)
 Treatment of precipitating factor(s)
 Avoidance of all CNS-acting medications

THYROID HORMONE REPLACEMENT

L-T₄: 200- to 300-μg loading dose IV, up to 500 μg IV in the first 24 h and/or
 L-T₃: 12.5 μg IV q 6 h

CNS, central nervous system; IV, intravenous.

the physician must have a high clinical index of suspicion for myxedema coma, as therapy must be instituted before the availability of thyroid function test results, in most cases.

Treatment

Treatment of myxedema coma is a medical emergency and should be managed in an ICU setting. The mainstays of therapy are supportive care with ventilatory and hemodynamic support, rewarming, correction of hyponatremia and hypoglycemia, treatment of the precipitating incident, and administration of thyroid hormone (Box 149-9).^{84,126,127} Sedatives, hypnotics, narcotics, and anesthetics must be minimized or avoided altogether because of their extended duration of action and exacerbation of obtundation in hypothyroid patients.

Hypothermia is one of the hallmarks of myxedema coma, and its severity may be underestimated if the thermometer used does not register below 30°C. At core temperatures below 28°C, ventricular fibrillation is a significant life-threatening risk. Despite its gravity, the management of the hypothermia of myxedema coma differs from the treatment of exposure-induced hypothermia in euthyroid subjects. In myxedema coma, patients should be kept in a warm room and covered with blankets. Active heating should be avoided, since it increases oxygen consumption and promotes peripheral vasodilation and circulatory collapse. Active heating is recommended only for situations of severe hypothermia where ventricular fibrillation is an immediate threat. In these cases, the rate of rewarming should not

exceed 0.5°C per hour, and the core temperature should be raised to approximately 31°C.^{84,126,127}

Because of a 5% to 10% incidence of coexisting adrenal insufficiency in patients with myxedema coma,¹⁴⁴ IV steroids (i.e., hydrocortisone 100 mg IV every 8 hours) are indicated before initiating L-T₄ therapy. Parenteral administration of thyroid hormone is necessary due to uncertain absorption through the gut.¹⁴⁵⁻¹⁴⁷ A reasonable approach is an initial IV loading dose of 200 to 300 μg of L-T₄. If there is inadequate improvement in the state of consciousness, blood pressure, or core temperature during the first 6 to 12 hours after administration, another dose of L-T₄ should be given to bring the total dose during the first 24 hours to 0.5 mg. This should be followed by 50 to 100 μg IV every 24 hours until the patient is stabilized. Alternatively, in the most severe cases, some clinicians recommend using L-T₃ at a dosage of 12.5 to 25 μg IV every 6 hours until the patient is stable and conscious. Caution must be used to avoid overstimulation of the cardiovascular system. Once stable, the patient should be switched to L-T₄. The dose of thyroid hormone should be adjusted on the basis of hemodynamic stability, the presence of coexisting cardiac disease, and the degree of electrolyte imbalance.¹⁴⁸

Although myxedema coma is associated with a high mortality, which may be as high as 40%,¹⁴⁹ survival can be maximized by correcting the secondary metabolic disturbances and reversing the hypothyroid state in a sustained but gradual fashion, since an effort to correct hypothyroidism too rapidly may completely negate the beneficial effects of the initial treatment.

Long-Term Therapy

Once the patient with myxedema coma is clinically stable, thyroid hormone replacement can be switched to oral L-T₄. The dose of L-T₄ should be adjusted over the ensuing weeks and months to achieve serum T₄ and TSH concentrations in the normal range.

CONCLUSION

In summary, thyroid storm and myxedema coma are medical emergencies, diagnosed by their clinical presentation and confirmed by serum thyroid function tests.¹⁵⁰ The interpretation of thyroid function tests in the ICU patient outside of these dramatic presentations is often fraught with difficulty. Identifying those patients with intrinsic thyroid dysfunction must take into consideration both the clinical assessment of the patient and the duration and severity of the illness. Whenever possible, it is best to defer evaluation of thyroid function until the patient has recovered from the critical illness.

Diabetes insipidus is a disorder of water metabolism associated with polyuria, urine hypotonicity, and hypernatremia.¹⁻³ The criteria for this diagnosis include urine output greater than 200 mL/h or 3 mL/kg/h, urine osmolality less than 150 mOsm/kg, and plasma sodium greater than 145 mEq/L. If urine osmolality measurement is not available, hypotonicity can be assessed from a urine specific gravity less than 1.005.

CENTRAL DIABETES INSIPIDUS

Neurogenic or central diabetes insipidus is characterized by a lack of antidiuretic hormone (ADH) that may result from any injury to the anterior hypothalamus, pituitary stalk, or posterior pituitary gland. In acute critically ill patients, the most common causes of diabetes insipidus are surgery for pituitary tumors, cerebral trauma, intracranial hypertension, and brain death (Box 150-1). Diabetes insipidus also may occur as a complication of bacterial meningitis or encephalitis, vascular aneurysm or thrombosis, drug administration, or alcohol intoxication. Injuries to the hypothalamus most often yield permanent diabetes insipidus because ADH is synthesized in the hypothalamus itself. Injuries to the pituitary stalk and neurohypophysis more commonly cause transient diabetes insipidus because hypothalamic ADH secretion can be effective even in the absence of anatomic pathways to the normal site of release. Chronic diabetes insipidus in critically ill patients generally results from tumors of the pituitary region and from the sequelae of cerebral trauma.

Clinical Picture

In complete hypothalamic or pituitary injuries, diabetes insipidus generally develops 6 to 24 hours after the injury because previously released ADH remains circulating for several hours. Patients with untreated diabetes insipidus usually develop urine output of 10 to 15 L/day. When the thirst mechanism is preserved, it is activated as soon as osmolality or volemia decreases. If the patient remains conscious and is given free access to water, he or she may be able to drink large amounts and compensate for the urine losses. In other cases, the large amounts of dilute urine rapidly result in dehydration with hypovolemia and hypotension as well as hypernatremia with neurologic deterioration. It is important that diabetes insipidus be recognized and treated rapidly, especially in comatose or noncommunicative patients. In patients with partial diabetes insipidus, the onset of polyuria may be delayed, and the volume of urine may be lower. Nevertheless, if urine is hypoosmolar and diabetes insipidus is not treated, dehydration and hypernatremia eventually occur and cause symptoms.

Clinical signs of hypernatremia usually appear only when the plasma sodium concentration increases to greater than 155 to 160 mEq/L or plasma osmolality increases to greater than 330 mOsm/kg.⁴ Signs may appear sooner if hypernatremia is associated with other metabolic disorders, particularly with disorders that also increase plasma osmolality. Symptoms mainly include confusion and lethargy. Severe hypernatremia results in coma and sometimes in seizures. Acute and severe dehydration and hypernatremia may lead to cerebral shrinkage, sometimes associated with subdural or intraparenchymal hemorrhage.

Clinical signs of dehydration include blood volume depletion and hypotension in the most severe cases. Biologic markers of dehydration

are usually absent in ICU patients with central diabetes insipidus because the urine loss begins abruptly and commonly reaches more than 1 L/h. The free water deficit can be estimated by the following formula:

$$\text{Deficit (L)} = \text{body weight (kg)} \times 0.6 \times (\text{Na}^+ - 140) / \text{Na}^+$$

This formula assumes that only free water has been lost and that sodium stores are normal. Most often, some sodium has been lost together with additional water, and the total water deficit is even higher than that estimated from the formula. A moderate level of hypernatremia (e.g., 155 mEq) is associated with a free water deficit of more than 4 L and total water deficit that may be much higher if sodium has been lost.

Differential Diagnosis

The differential diagnosis of polyuria includes the intake of diuretic drugs, hyperglycemia, fluid overload, and fluid mobilization. The search for diuretic administration should include not only conventional diuretics but also mannitol and iodinated contrast agents. The administration of diuretics may not be evident when these substances have been given before admission to the ICU (e.g., in another hospital before patient transfer; in an ambulance during transfer; or in the operating room during neurosurgery, trauma surgery, or vascular surgery). Preventive administration of furosemide and mannitol is given routinely in some neurosurgical procedures and may result in marked polyuria during and after the operation. Hyperglycemia-induced osmotic diuresis is common, can be suspected from polyuria or from hyperglycemia, and is confirmed or ruled out by the presence or absence of glucosuria. Hypervolemia, resulting from fluid overload or unmasked by discontinuation of sustained positive-pressure ventilation, may increase urine output to greater than 5 L/day for several days in patients with normal renal function. Mobilization of edema, at the time of recovery from disease or from surgery, also can result in sustained polyuria. In all these conditions, however, urine remains close to isotonic (osmolality ~300 mOsm/kg). Abundant intake of hypotonic fluid can cause polyuria and urine hypotonicity but does not result in hypernatremia if renal function is normal. The observation of decreased urine output after ADH administration is not diagnostic of diabetes insipidus because ADH is able to reduce urine output and to increase urine osmolality in all conditions except nephrogenic diabetes insipidus.

Treatment

The management of diabetes insipidus includes two components (Box 150-2): (1) reduction of excessive urine output and (2) correction of water deficit. The polyuria of central diabetes insipidus is treated effectively by vasopressin (ADH) or by its synthetic analog desmopressin acetate (DDAVP [1-deamino-8-D-arginine vasopressin]).^{5,6} As indicated by its multiple names, vasopressin not only has antidiuretic but also vasoconstrictive and oxytocic effects, whereas desmopressin essentially retains the antidiuretic action. The effects of aqueous vasopressin (4 to 10 U subcutaneously or intramuscularly) on diuresis begin rapidly but last for only a few hours. Dosing of vasopressin must therefore be repeated every 4 to 6 hours and has been recommended only for diagnostic purposes or in acute conditions (e.g., trauma) in

NEPHROGENIC

Congenital disease
 Renal disease: obstructive uropathy, reflux nephropathy, cystic disease, electrolyte disorders
 Renal involvement in systemic disease: sarcoidosis, amyloidosis, sickle cell disease
 Drugs: phenytoin, aminoglycosides, amphotericin, antivirals, demeclocycline, lithium

BOX 150-2 Management of Diabetes Insipidus

Control polyuria with DDAVP or vasopressin.
 Calculate and replace free water loss.
 Monitor and replace urine losses hourly.
 Monitor plasma electrolytes and adapt therapy every 4 h.

DDAVP, 1-deamino-8-D-arginine vasopressin.

which the diabetes insipidus might be transient. The effects of vasopressin tannate in oil emulsion (2 to 5 U intramuscularly) last 48 to 96 hours, but the preparation requires close attention to warming and mixing the suspension before injection. Vasopressin tannate previously used to be the standard therapy in patients with central diabetes insipidus but now has been abandoned in favor of desmopressin. Vasopressin tannate, where available, still may be used in patients who are refractory to desmopressin or who experience significant side effects. Desmopressin has prolonged effects (8 to 20 hours) and is appropriate for intravenous, subcutaneous, and intranasal routes. Lypressin is another ADH analog that is appropriate for intranasal use, but its effectiveness is limited by its duration of action of only 4 to 6 hours. Desmopressin is known to increase factor VIII and von Willebrand factor levels and is sometimes used for this reason in patients with coagulation disorders or in the setting of surgical procedures associated with significant bleeding.

In critically ill patients with acute central diabetes insipidus, desmopressin is initially given as 10 to 20 µg intranasally and repeated every 30 to 60 minutes until urine output is reduced to less than 100 mL/h. The initial dose required to maintain a normal urine volume ranges from 10 to 60 µg in most patients. This dose is given again when the urine output increases to greater than 200 mL/h (i.e., after 8 to 24 hours). Dosage must be reduced if urine output is excessively decreased. The subcutaneous route is seldom used because absorption may be erratic in vasoconstricted patients and because an intravenous line is virtually always available in ICU patients. Desmopressin is injected intravenously when the intranasal route is not available (i.e., in cases of rhinorrhea and facial trauma). The required initial dose ranges from 2 to 20 µg and is given as repeated 2- to 4-µg boluses.

Vasopressin therapy can be associated with arterial hypertension, myocardial infarction, mesenteric infarction, peripheral ischemia, and uterine cramps. Vasopressin tannate may cause allergic reactions, ranging from urticaria to anaphylaxis, and sterile abscesses at sites of injection. Desmopressin may interfere with anticoagulant drugs and cause hypercoagulability. When given in excess, all these antidiuretic

agents can result in oliguria, hyponatremia, and water intoxication. The severity of diabetes insipidus may vary over time, even in patients with chronic diabetes insipidus, and some patients with chronic diabetes insipidus who are used to drinking large amounts of water may continue to do so even if urine output is limited by a diuretic drug.

Patients with acute diabetes insipidus should receive a sufficient amount of water to match urine output until the polyuria is controlled and to correct the deficit of free water that already exists at the time of diagnosis. If the gastrointestinal system is functional, water can be infused at rates of 1 to 2 L/h through a gastric tube. Otherwise, isotonic dextrose should be infused intravenously in appropriate amounts (hypotonic dextrose administration can be obtained by infusing equal amounts of water and isotonic dextrose in a central vein, but this procedure has been associated with vascular injuries). The gastric or intravenous infusion rate is adjusted at least hourly to match urine output of the last equivalent period. Plasma electrolytes should be monitored every 4 hours until normal sodium levels are restored and stabilized. Blood glucose must be monitored closely and hyperglycemia treated aggressively using intravenous insulin. Failure to control hyperglycemia may be associated with osmotic diuresis due to glucosuria and superimpose an equivalent of diabetes mellitus on the already present diabetes insipidus.

NEPHROGENIC DIABETES INSIPIDUS

Nephrogenic diabetes insipidus is characterized by the inability of the renal parenchyma to concentrate urine in response to ADH.^{7,8,9} The disorder is seldom diagnosed in the ICU and is usually more severe when it is congenital. Hereditary forms generally result from mutations to the AVP-2 receptors or AQP-2 water channels. Acquired forms are due to vasopressin resistance of the distal tubule and collecting duct or to markedly reduced renal concentrating capacity. Most acquired forms are attributed to electrolyte disturbances and to lithium therapy, but many other drugs have been implicated. Nephrogenic diabetes insipidus may be treated with a low-sodium low-protein regimen that reduces the solute load, with thiazide diuretics that induce a mild volume depletion and help reduce the urine volume to acceptable values, and with nonsteroidal antiinflammatory drugs, such as indomethacin, that inhibit prostaglandin synthesis.

KEY POINTS

1. Diabetes insipidus is characterized by polyuria, urine hypotonicity, and hypernatremia.
2. Central diabetes insipidus results from a lack of antidiuretic hormone (ADH); nephrogenic diabetes insipidus results from renal insensitivity to ADH.
3. In the ICU, diabetes insipidus is caused mainly by pituitary surgery, trauma, and brain death.
4. Clinical signs are related to dehydration and hypernatremia.
5. ICU patients generally are unable to compensate for excessive urine losses by drinking.
6. Differential diagnosis includes administration of diuretics, mannitol, and iodinated agents.
7. Polyuria is controlled with desmopressin, 10 to 20 µg intranasally or 2 to 4 µg intravenously.
8. Water deficit is corrected with enteral water or intravenous 5% dextrose in water.
9. Diuresis should be monitored hourly, and ongoing urinary losses should be compensated.

Increasing numbers of metabolic and endocrine conditions are being recognized, and the number of children in treatment programs for these conditions is increasing. Although improved screening programs and therapy may decrease the number of children requiring critical care for these conditions, it is likely that these conditions will be recognized with larger numbers of critically ill children in the future. There is growing awareness of the significance of metabolic changes such as hypo- and hyperglycemia in the pediatric intensive care unit (PICU),¹ of the endocrine associations with medications such as etomidate² and conditions such as traumatic brain injury,^{3,4} and of the importance of vitamins such as vitamin D (which functions as a steroid hormone) in critical illness.⁵

General principles of PICU management apply to patients with endocrine and metabolic crises (Table 151-1).^{6,7} Crises may cause damage with long-term sequelae for the child and family; however, they also present unique diagnostic opportunities. Intensivists have a responsibility to

- Be aware of metabolic and endocrine problems
- Consider these problems in the differential diagnosis of particular clinical syndromes
- Perform appropriate clinical and biochemical investigations (this may include investigations necessary to make a diagnosis despite a poor outcome for a child)
- Seek advice from specialists in the clinical and laboratory diagnosis and management of the conditions
- Consider the implications of metabolic and endocrine problems for the family of the affected child⁸
- Support the development of protocols for the comprehensive management of metabolic problems from infancy to adulthood⁹

Abnormalities of glucose control are common in the PICU, but with the possible exception of diabetes mellitus, endocrine and metabolic crises are uncommon, and most intensivists do not see sufficient case numbers to become experts at managing these disorders. It is thus crucial to manage children with suspected or proven endocrine or metabolic crises in conjunction with specialist teams. The laboratory investigation of inborn errors of metabolism (IEM) may be complex, and there are few laboratories worldwide that have the capacity to fully elucidate most of the IEM. Close cooperation with specialty laboratory centers is essential for accurate diagnosis and management. A specific challenge of endocrine and metabolic crises is that laboratory investigation of specific conditions may take time, while patients require urgent treatment. Because it may not always be possible to closely follow algorithms of investigation, a reasonable laboratory approach is to collect relevant specimens immediately,¹⁰ store them appropriately, and liaise with laboratory services to use the specimens in a logical and cost-effective manner to confirm the diagnosis.

■ ENDOCRINE CRISES

Endocrine crises present in a limited number of ways that include abnormalities in glucose control, fluid and electrolyte balance, and blood pressure control. Management consists of identifying the problem, investigating the cause, and correcting the abnormality directly or via managing the underlying problem. This chapter provides an overview of pediatric endocrine crises.

Abnormalities of Glucose Control

Abnormalities of glucose control, including diabetic ketoacidosis (DKA), are the most common endocrine crises encountered in the PICU. Hypoglycemia¹¹⁻¹³ and hyperglycemia^{1,14} are associated with increased mortality and morbidity in sick children and may be part of a wide variety of disease processes. Measurement of blood glucose level is part of the initial biochemical evaluation of any sick child, particularly if a depressed level of consciousness or shock is present. When an abnormal glucose level is identified, it must be addressed and reassessed at appropriate intervals until the problem is resolved. The situation is complicated by technical issues in the measurement of blood glucose levels,¹⁵⁻¹⁷ with differences between blood and plasma glucose levels and between arterial, venous, and capillary glucose levels (which may also vary depending on clinical context) and potentially significant differences among different measurement techniques.¹⁵ In general, a specific concern is that inaccuracies tend to increase at lower glucose levels.¹⁵ Central laboratory measurements are generally taken as the standard, although there is increasing utilization (and convenience) of point-of-care devices.

Hypoglycemia

Hypoglycemia may be associated with devastating damage to the brain and requires immediate attention. A diagnosis of hypoglycemia depends on the presence of (1) symptoms consistent with hypoglycemia, (2) a low blood glucose level, and (3) resolution of symptoms with correction of the low glucose level. Unfortunately, symptoms of hypoglycemia are non-specific (ranging from lethargy, poor feeding, hypotonia, and "jitteriness" to convulsions, apneic episodes, cardiovascular collapse, and sudden infant death syndrome [SIDS]) and may be hidden in the complexity of critical illness, particularly if patients are deeply sedated and/or paralyzed. Some diabetic patients have reduced awareness of hypoglycemia.¹⁸ Thus, regular monitoring of blood glucose levels is an important part of the management of any critically ill child, although the implications of a particular level may also be related to the availability of other energy sources such as ketones.¹⁹ Although the exact definition of hypoglycemia in children is controversial, a minimal level of 2.6 mmol/L or greater should be maintained to ensure normal neural function.^{20,21} It probably is safer to maintain a level higher than 3.5 mmol/L. Because there are multiple causes for hypoglycemia and symptoms may not be due to the hypoglycemia alone, it is essential to identify the cause of hypoglycemia.

In childhood, hypoglycemia may result from inadequate glucose intake (prolonged starvation, malabsorption), defects in glycogenolysis (glycogen storage disorders) or gluconeogenesis (fructose-1,6-diphosphatase deficiency, ethanol intoxication, Jamaican vomiting sickness, etc.), fatty acid oxidation disorders and defects in ketogenesis, a deficiency of gluconeogenic hormones (such as adrenaline, corticosteroids, glucagons, growth hormone, and thyroid hormone), excessive insulin secretion (hyperinsulinism), or a variety of specific disorders including abnormalities of amino acid metabolism.²²

The amount of glucose required to achieve normoglycemia and the duration of fast that can be endured without the development of hypoglycemia may assist in identifying a likely cause. Transient hypoglycemia that can be reversed with normal infusion rates of glucose (4 to 6 mg/kg/min) and does not recur is unlikely to be associated with

TABLE 151-1 Principles of Management of Metabolic and Endocrine Crises

| PRINCIPLE | SPECIFICS OF CONDITIONS |
|---|--|
| Airway management | Many patients have depressed level of consciousness, and airway management is essential to prevent complications. |
| Breathing support | Acidotic patients may make huge respiratory effort; ventilatory support may help to decrease the metabolic demands on these patients. Although administration of sodium bicarbonate may help to settle some of the acidosis-related symptoms, such as hyperventilation, bicarbonate may aggravate some problems seen in conjunction with urea cycle defects. Give bicarbonate only if the plasma bicarbonate is <10 mmol/L and then only correct deficits by half. |
| Circulatory support | Ensure that there is adequate circulating volume; this may be a particular issue if there has been excessive fluid loss from vomiting or diarrhea. |
| Disability | Control seizures using anticonvulsant agents. Administer pyridoxine if there is a possibility of pyridoxine dependency. |
| Dialysis to remove toxins where necessary | Hemodialysis is the most efficient means of removing toxins such as ammonia and leucine. Hemofiltration is less efficient but may be more applicable in critically ill children. Peritoneal dialysis is slower but has the advantage of ease of initiation. ²²³ In some conditions, it may be possible to remove toxins by stimulating alternative pathways of metabolism. |
| Ensure that glucose is maintained in the normal range | A normal glucose level should be maintained at all times. Excessive administration of glucose in the mitochondrial energy chain problem may exacerbate lactic acidosis. Also, attempt to provide an adequate energy supply (may use medium-chain fatty acids where appropriate). Minimize energy demands on patient. |
| Fluids | In general, provide 1.5× the normal fluid maintenance requirements to accelerate excretion of water-soluble toxins. In the context of encephalopathy (MSUD or urea cycle defects), be careful to avoid overhydration, which may exacerbate cerebral edema. |
| Feeds | If there is accumulation of a product, this needs to be eliminated from the diet (e.g., fructose, galactose). Start with a protein-free diet, but do not continue that beyond 2 days because the catabolic state also creates problems. If a diagnosis not identified, gradually reintroduce feeds and nutrition. If there is a deficiency of any nutrient (e.g., carnitine, which may have a primary or a secondary deficiency), supplement that nutrient. Ensure that there is an adequate energy source along a metabolic route that is functional. Provide specific vitamin therapy where indicated. |
| Family support and information | The diagnosis of an inborn error of metabolism (IEM) has major implications for families, and considerable support is required. ² |
| Treat infection | Infections are an important component of pediatric ICU presentation of inborn errors of metabolism. Some conditions, such as galactosemia, are related to specific infections, such as <i>Escherichia coli</i> . Other conditions are related to pyogenic infections because of neutropenia. Children who are in a poor nutritional or metabolic state are more susceptible to infection. Concomitant infections may be the precipitating factor for metabolic decompensation. |
| Investigations | A wide variety of investigations are relevant to IEMs. Biochemical testing on a range of body fluids and on tissues is fundamental to the accurate diagnosis of the problem; tests may range from screening to more complex tests on tissue culture. Imaging, such as CT, MRI, magnetic resonance spectroscopy, and echocardiography, may be relevant. Functional tests, such as EEG, ECG, and EMG, may be useful in establishing a diagnosis. Increasingly, genetic diagnosis is available, if children have recognized genetic mutations. |
| Monitor response to therapy | Clinical monitoring is essential. Biochemical monitoring of the appropriate metabolites is essential to ensure that metabolic control is established. |

CT, computed tomography; ECG, electrocardiogram; EEG, electroencephalogram; EMG, electromyogram; ICU, intensive care unit; MRI, magnetic resonance imaging; IEM, inborn error of metabolism.

an endocrine problem. Hyperinsulinemia is associated with the rapid development of hypoglycemia and high glucose requirements (>6 to 8 mg/kg/min to >15 to 20 mg/kg/min). Hypoglycemia associated with adrenal insufficiency, growth hormone deficiency, and hypothyroidism tends to occur several hours after fasting, is associated with ketosis, and can be reversed with normal infusion rates of glucose. Fatty acid oxidation defects are associated with hypoglycemia after a fast of several hours. Alternatively, hypoglycemia within 1 to 3 hours of a meal is usually related to hyperinsulinemia, within 4 to 5 hours of a meal signifies problems of glycogenolysis, and after 12 or more hours of fasting signifies problems in gluconeogenesis.²³

As soon as hypoglycemia is noted (and confirmed), specimens should be collected immediately for appropriate testing (Table 151-2). Treatment of hypoglycemia with intravenous glucose should be initiated promptly. An initial bolus dose of 0.5 g/kg of glucose (neonates may require 0.5 to 2 g/kg) should be given as a 10% or 25% (25% in older children) dextrose solution, followed by an ongoing infusion of glucose at a rate of 4 to 8 mg/kg/min. The concentration of the ongoing infusion depends on the fluid requirements of the child and the availability of central venous access (for higher concentrations). Glucagon may be given at a dose of 0.1 to 0.3 mg/kg (intravenously or intramuscularly) but is unlikely to be effective in patients with low glycogen stores, glycogen storage disorders, or hepatic dysfunction.²³ Hydrocortisone at a dose of 5 mg/kg every 12 hours may be useful in some patients. Diazoxide and intravenous octreotide decrease insulin release and may be useful in the management of hyperinsulinemia.

If non-glucose-reducing substances are present in the urine, galactosemia, hereditary fructose intolerance, or tyrosinemia should be considered. In the absence of reducing substances, low urinary ketones with hypoglycemia suggest hyperinsulinism or defects of fatty acid oxidation. The latter can be distinguished from hyperinsulinemia by the presence of high levels of serum free fatty acids. Assays of insulin levels can confirm the diagnosis of hyperinsulinism.

Abnormalities in growth hormone, cortisol, or thyroid hormone typically are associated with high levels of urinary ketones, the absence of hepatomegaly, and increased levels of lactate. Hypoglycemia may also occur as a complication of insulin therapy for diabetes mellitus. Patients with diabetes mellitus may have inadequate responses to hypoglycemia.

Neonates. Hypoglycemia immediately after birth may be common, but there are controversies in its definition.²⁴⁻³¹ The current recommendation for the definition of hypoglycemia in the period after birth includes a single measurement of blood glucose level less than 1 mmol/L (18 mg/dL), blood glucose level less than 2 mmol/L (36 mg/dL) that remains below the same value at the next measurement, or a single measurement of less than 2.5 mmol/L (45 mg/dL) in a newborn with abnormal clinical signs.³¹

In the immediate newborn period, glucose is not the only energy source from oxidative metabolism in the brain, and alternative energy sources such as ketones may be used.³² Breastfed babies routinely have lower glucose levels and higher ketone levels than formula-fed infants. However, there is evidence that hypoglycemic injury is more likely to occur at very low levels of glucose (20 to 25 mg/dL, 1.1 to

TABLE 151-2 Investigation of Hypoglycemia

| TEST | COMMENT |
|---|--|
| Blood glucose | Measurement of glucose using blood from capillary specimens and using test strips may be unreliable (particularly in poorly perfused patients or patients with high hematocrit); where possible, low glucose levels should be confirmed using laboratory assays on venous or arterial blood. |
| Calculation of actual glucose intake | Hypoglycemia in the presence of normal glucose intake or after brief fast suggests hyperinsulinism. Hypoglycemia after hours of fasting is associated with fatty acid oxidation defects and endocrine insufficiency. |
| Non-glucose-reducing substances in the urine | Particularly in neonates and probably not relevant in older children. If present in the urine, consider galactosemia, hereditary fructose intolerance, or tyrosinemia. |
| Serum and urinary ketones | Low ketones suggest hyperinsulinism or fatty acid oxidation problems. |
| Serum free fatty acids | Free fatty acids are low in hyperinsulinism but high in fatty acid oxidation defects. |
| Serum insulin (and C peptide), cortisol, glucagon, growth hormone, and thyroid levels | Normal serum insulin in the presence of hypoglycemia is evidence of hyperinsulinism. C peptide may be necessary to ascertain whether exogenous insulin was administered. Release of C peptide may not be as pulsatile as that of insulin. |
| Serum ammonia | Used to recognize hyperinsulinism/hyperammonemia syndrome. |
| Urinary organic acids and serum amino acids | Used to diagnose fatty acid oxidation defects (urinary organic acids). Aminoacidopathies such as MSUD, propionic acidemia, isovaleric acidemia, methylmalonic acidemia, and tyrosinemia may also present with hypoglycemia. |
| Total and free carnitine with acylcarnitine profile | To recognize primary and secondary deficiency of carnitine and fatty acid oxidation defects. |

1.4 mmol/L), if hypoglycemia is prolonged, if hypoglycemia is the consequence of hyperinsulinemia (when alternative energy sources for the brain may be very limited), and in the presence of other potential injuries.^{28,33}

Infants at particular risk include those with poor hepatic glycogen stores (e.g., preterm or small for gestational age infants), poor glucose intake (e.g., preterm or ill infants), and hyperinsulinism, either primary or secondary to high intrauterine glucose levels (e.g., infants of diabetic mothers).³⁴ Hypoglycemia may also be a feature of perinatal illness, including asphyxia, polycythemia, hypothermia, septicemia, and respiratory distress syndrome. Much less common causes include growth hormone³⁵ or adrenal insufficiency,³⁶ IEM, and glucagon insufficiency. Drugs administered to the mother during pregnancy, including oral hypoglycemic agents, must also be considered. Although the threshold for treatment in an asymptomatic neonate is 25 to 30 mg/dL (0.1 to 1.4 mmol/L), the recommended levels during treatment are higher than 45 mg/dL (2.5 mmol/L).

Hypoglycemia is associated with severe illness. A variety of illnesses, including infections,³⁷ cyanotic and acyanotic congenital heart disease, and cardiomyopathy/myocarditis, are associated with hypoglycemia. Hepatic failure from infection, toxin ingestion, or drug reactions may be associated with severe hypoglycemia, and individuals with Reye syndrome classically present with hypoglycemia. Toxins, such as salicylates and ethanol, may also cause hypoglycemia. Hypoglycemia has been linked with increased mortality from malaria,³⁸⁻⁴⁰ gastroenteritis,⁴¹ and acute bacterial meningitis,⁴² among other conditions. Hypoglycemia has also been described as a complication of

therapy for leukemia with mercaptopurine and methotrexate.^{43,44} Although severe illness or sepsis may be an adequate explanation for hypoglycemia, a diagnosis of sepsis should not exclude the possibility of an endocrine or metabolic crisis.

Hyperinsulinemic Hypoglycemia

Hyperinsulinism is the most common cause of persistent or recurrent hypoglycemia in infancy. It may be secondary to risk factors in the perinatal period (associated with high maternal glucose levels,⁴⁵ rhesus incompatibility, intrauterine growth retardation,⁴⁶ and perinatal asphyxia)⁴⁷ but may also be congenital⁴⁸ or associated with syndromes such as Beckwith-Wiedemann, Sotos, Kabuki, Costello, or Turner (mosaic), with congenital deficiency of glycosylation, among others.⁴⁹ Although most patients with hyperinsulinemic hypoglycemia present in the neonatal period, the first presentation may be during infancy and occasionally during childhood⁵⁰ when it may be more likely to respond to medical therapy. Neonates with hypoglycemia may have macrosomia typical of infants of diabetic mothers, but hyperinsulinemic hypoglycemia may occur in apparently normal infants of normal or low birth weight. Hypertrophic cardiomyopathy and hepatomegaly may be seen⁵¹ in affected infants. The characteristic features of hyperinsulinism include hypoglycemia with onset soon after feeds, glucose requirements of greater than 6 to 8 mg/kg/min to maintain normoglycemia, absence of ketonemia and ketonuria, low levels of plasma free fatty acids and branched-chain amino acids, detectable insulin levels at the time of hypoglycemia (there are a range of reported insulin levels during hypoglycemia in these patients),²³ and a positive response to glucagon therapy.⁵¹ The combination of hypoglycemia with low levels of free fatty acids and the absence of ketonemia is responsible for the potentially devastating effects of this condition on the brain as it is deprived of both normal and alternate substrates.⁵²

Transient hyperinsulinemic hypoglycemia is relatively common in small for gestational age infants and those with perinatal stress²³—this may relate to the inhibition of islet cell function in utero by hypoxia-inducible factor 1 α ,⁵³ with subsequent disinhibition once normal oxygenation occurs after birth. Transient hyperinsulinemic hypoglycemia may also be related to HNF4A mutations. These patients have a higher incidence of macrosomia⁵⁴ and may go on to develop maturity-onset diabetes of the young.⁵⁵ Congenital hyperinsulinemic hypoglycemia is caused by abnormalities in genes controlling the secretion of insulin by beta cells of the pancreas, with abnormalities described in nine genes,⁵⁶ although up to 21% of patients with ongoing congenital hyperinsulinemic hypoglycemia have no identifiable gene abnormalities.⁵⁷ Although the relative frequency of mutations is related to specific populations, the most common group has inactivating mutations in one of the K_{ATP} channel genes. Hyperinsulinemic hypoglycemia with hyperammonemia (previously called leucine-sensitive hypoglycemia) is well described^{58,59} and is attributed to mutations in the gene for glutamate dehydrogenase. Patients generally respond well to therapy with diazoxide, and consumption of extra carbohydrate before protein meals may help ameliorate symptoms. Special low-leucine milks are available. There is, however, also an association with seizure activity in affected children.⁵⁸

Initial stabilization consists of glucose infusions to achieve normoglycemia. Because there may be extremely high glucose requirements, and any cessation of infusion may be associated with severe hypoglycemia, it is essential to ensure that secure vascular access is *always* available; central venous access may be required in these cases. Glucagon (0.5 to 1 mg/kg as an emergency intramuscular [IM] or subcutaneous [SQ] dose,⁶⁰ intravenous [IV] bolus, or as an IV infusion 1 to 20 μ g/kg/h) must always be available and can be used as short-term, emergency therapy to maintain normoglycemia if there are problems with vascular access. Administration of glucagon may be associated with rebound hypoglycemia, and frequent glucose monitoring must be continued. Octreotide (5 to 30 μ g/kg/day SQ or as an IV infusion) may also be given together with glucagon but may be associated with an increased risk of enterocolitis as well as other complications such as

hepatitis^{61,62} or long QT syndrome.⁶³ As soon as normoglycemia has been achieved, the child should be transported to a center with expertise in management of hyperinsulinemia. Care must be taken to ensure that hypoglycemia does not occur during transport. The aim of further management is to confirm the diagnosis and ensure normoglycemia (keep glucose levels >3.5 mmol/L in view of low alternative sources of energy) without the ongoing use of glucose infusions. Glucose polymers can be added to the diet to provide an enteral source of glucose, but care must be taken to limit the osmolar load on the gut, particularly in premature infants.

Clinically, hyperinsulinemic hypoglycemic patients may be categorized by their response to diazoxide (5 to 20 mg/kg/day orally in two to three divided doses) with most responding—exceptions include those with congenital hyperinsulinemia related to focal hyperinsulinemia and those with diffuse hyperinsulinemia related to inactivating mutations in *ABCC8* and *KCNJ11*. Unfortunately, diazoxide may predispose to fluid retention, and its use must be carefully monitored. Chlorothiazide (7 to 10 mg/kg/day in 2 divided doses) may be added (particularly in neonates).⁵² There are also reports of paradoxical hypoglycemia related to high-dose diazoxide therapy.⁶⁴ Nifedipine (0.25 to 2.5 mg/kg/day in three divided doses) may be useful in this case.^{65,66}

An approach to ongoing diagnosis and management is outlined in Figure 151-1. In patients who are responsive, diazoxide will remain the

basis of therapy. In those with no response to diazoxide, genetic testing (for homozygous or compound heterozygous mutations in *ABCC8* and *KCNJ11*), followed by ^{18}F -DOPA positron emission tomography (PET) scanning for those with potentially focal pancreatic lesions will enable identification of those who may benefit from resection of the pancreas. Pancreatic islet cells take up L-3,4-dihydroxyphenylalanine (L-DOPA), where it is converted to dopamine by DOPA decarboxylase. Uptake of the positron-emitting tracer ^{18}F -DOPA PET is increased in beta cells with a high rate of insulin synthesis, and secretion provides visualization of the focal lesion.^{67,68} Patients with focal lesions should respond to partial pancreatectomy (although identification of the focal areas may be difficult at the time of surgery), which may be done laparoscopically.^{69,70} Diffuse disease that is unresponsive to diazoxide therapy will require a near-total pancreatectomy⁷¹ and may be associated with a high incidence of endocrine and exocrine problems. Close long-term follow-up is required in all of these patients, and there may be neurologic and psychologic problems that require management.

Ketotic Hypoglycemia

Although ketotic hypoglycemia (“accelerated starvation”) is probably the most common cause of hypoglycemia in previously healthy children,⁷² it is unlikely to present in the PICU. It usually affects children aged 6 months to 8 years, and features include ketosis, severe nausea,

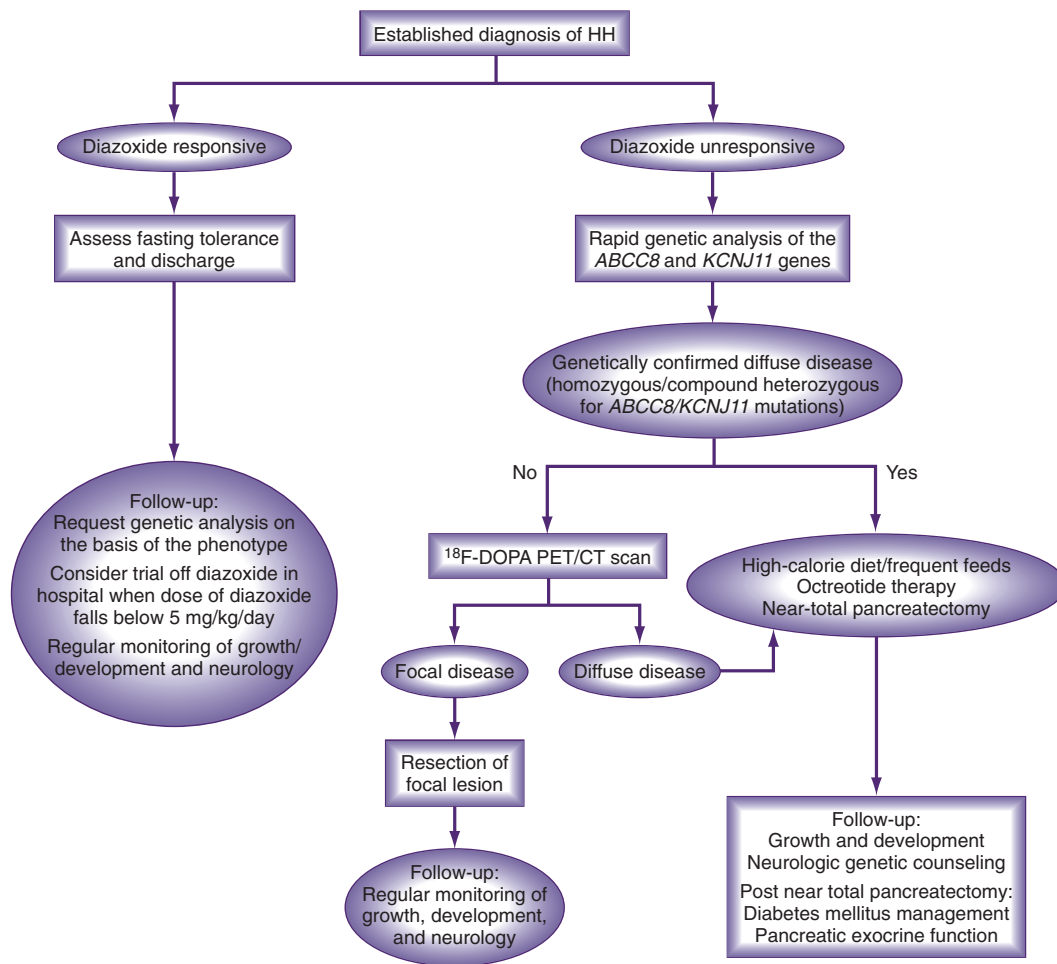

FIGURE 151-1 ■ Flow chart outlining the management cascade of neonates with hyperinsulinemic hypoglycemia (HH). Clinically, HH can be classified into diazoxide-responsive and diazoxide-unresponsive disease. A fluorine-18 L-3, 4-dihydroxyphenylalanine positron emission tomography (^{18}F -dopa PET) scan is currently only indicated in neonates who are unresponsive to diazoxide and do not have genetically confirmed diffuse disease. (From Kapoor RR, Flanagan SE, James C, et al. Hyperinsulinaemic hypoglycaemia. Arch Dis Child 2009;94:450–457.)

and hypoglycemia, usually occurring in the morning after a moderate fast. Treatment consists of ensuring that there is an adequate and regular intake of glucose, particularly during concomitant infection. Ketosis usually precedes the onset of hypoglycemia by several hours.

Adrenal Insufficiency

Adrenal insufficiency after high-dose inhaled corticosteroid therapy has presented with hypoglycemia⁷³ and should be considered if there is a history of inhaled steroid use. Similarly, adrenal insufficiency may follow treatment for childhood malignancy such as leukemia.⁷⁴ Adrenal insufficiency may also occur after adrenal bleeds (e.g., after meningococcal septicemia or difficult delivery), as part of adrenal disease (e.g., congenital adrenal hyperplasia or hypoplasia) in which ambiguous genitalia may (or may not) be a finding in females, or as part of hypopituitarism (e.g., congenital, after craniopharyngioma resection, or after cranial irradiation).⁷⁵ Some patients with primary adrenal insufficiency may also present with hypoglycemia, particularly during acute illnesses.^{36,76} Adrenoleukodystrophy should be considered as part of the etiology in a male patient with Addison's disease (pigmentation may be a clue) and should be tested for by measurement of very long-chain fatty acids.⁷⁷

There has been great interest in adrenocorticoid deficiency in children with critical illness and particularly in acute, severe sepsis (see Chapter 122).⁷⁸ Currently, supplementary steroids are recommended for children with acute, severe sepsis and suspected or proven adrenal insufficiency,⁷⁹ but there are not clear definitions for adrenal insufficiency or catecholamine resistance, nor are there definitive recommendations for the dose of adrenal replacement therapy.⁸⁰

Adrenocorticoid deficiency (both relative and absolute) has also been seen in preterm infants,^{81,82} but there is no consensus on definitions and the need for steroid therapy.⁸³ There is evidence that hypotensive preterm infants improve blood pressure with hydrocortisone therapy but the impact on long-term outcome is not known.⁸⁴

Congenital adrenal hyperplasia is rarely associated with hypoglycemia. Female patients are usually diagnosed early in life as a result of virilization, whereas male patients tend to present later. Patients with the salt-losing form of congenital adrenal hyperplasia present with hyponatremic dehydration and shock, usually associated with hyperkalemia. Because patients with salt-wasting 21-hydroxylase deficiency may also have catecholamine deficiency, shock may be seen. Diagnosis is based on the clinical presentation, typical electrolyte pattern, hypoaldosteronism, and hyperreninemia.⁸⁵ Long-term treatment consists of hydrocortisone (to suppress excess secretion of corticotropin-releasing hormone and corticotropin), together with mineralocorticoid replacement and sodium chloride supplementation.⁸⁶ Little is known about the dose of hydrocortisone required during critical illness, although Charmandari et al.⁸⁷ showed that when 6-hourly bolus doses of 15 mg/m² of hydrocortisone are given, high immediate serum levels are achieved, followed by a rapid decline to undetectable levels by 4 hours after administration. They postulated that continuous infusion of hydrocortisone might be more appropriate in critical illness.

Growth Hormone Deficiency

In the neonatal period, growth hormone deficiency presents with hypoglycemia (possibly with seizures),⁸⁸ prolonged jaundice, and micropenis and undescended testes in boys. Growth failure becomes apparent only toward the end of the first year of life. In later childhood, growth failure is a more common presentation, and hypoglycemia rarely occurs unless associated with adrenocorticotrophic hormone deficiency.

Hyperglycemia Other Than Diabetes Mellitus

Hyperglycemia is relatively common in the PICU⁸⁹ in a variety of conditions including bronchiolitis,⁹⁰ sepsis, hemolytic uremic syndrome,⁹¹ tetanus,⁹² and toxin ingestion (e.g., theophylline poisoning),⁹³ and a number of studies have shown an association between

hyperglycemia and increased mortality in critically ill children⁹⁴⁻⁹⁷; however, this has not been confirmed in all studies.^{95,98} Glucose variability has also been associated with increased mortality, length of hospital stay, and infection in critically ill children.⁹⁹

Iatrogenic causes of hyperglycemia in the PICU include resuscitation using glucose-containing fluids, parenteral nutrition or a high load of administered glucose, and high-dose corticosteroid therapy. Persistent hyperglycemia may also be an indication of ongoing stress or undiagnosed type 1 diabetes and should prompt the clinician to investigate further.

An initial report from an adult surgical unit (predominantly cardiac)¹⁰⁰ suggested that "tight" control of glucose levels was associated with a significant improvement in patient outcomes. Subsequently, glucose control using insulin therapy was instituted in many ICUs across the world, with several studies supporting the initial findings. Unfortunately, there have been increased reports of iatrogenic hypoglycemia, and meta-analyses of studies in adults^{101,102} concluded that tight glucose control was not associated with an improvement in hospital mortality and was associated with an increased incidence of hypoglycemia. Subsequently, a large randomized controlled trial (RCT) of adult patients¹⁰³ compared "tight" (81 to 108 mg/dL or 4.5 to 6.0 mmol/L) with "conventional" glucose control (target of ≤ 180 mg/dL or ≤ 10.0 mmol/L). The 90-day mortality was higher in the group on tight glucose control, and subgroup analysis showed that outcomes favored conventional control in all groups except trauma patients and patients on steroids. A meta-analysis¹⁰⁴ subsequently concluded that intensive insulin therapy in critically ill patients increased the risks of hypoglycemia and provided no reduction in mortality for critically ill patients with the possible exception of patients in a surgical ICU.

There have been a number of RCTs of intensive insulin therapy to maintain tight glucose control in pediatric critical care¹⁰⁵⁻¹⁰⁸ (including children post cardiac surgery, post burn injury, and those admitted to the PICU for a variety of other reasons) with varying results. These have been reviewed in a meta-analysis,¹⁰⁹ and the authors concluded that there is no evidence that tight glucose control using insulin therapy is associated with an improvement in 30-day mortality in critically ill children; however, there may be a reduction in the rate of acquired infection. There was an increase in hypoglycemic events in patients treated with insulin therapy to maintain tight glucose control except in the trial that used continuous glucose monitoring,¹¹⁰ and in one study hypoglycemia was associated with increased mortality.¹⁰⁸ An intriguing finding in one study¹¹¹ was that in patients who were not admitted to the PICU following cardiac surgery, there was a \$13,000 reduction in healthcare costs over a 12-month period in those who had received intensive insulin therapy.

These studies highlight the technical problems associated with reliable monitoring of blood glucose levels in the ICU environment.¹¹² A recent review¹¹³ concluded, "Hence, efficacy and safety of intensive insulin therapy may be affected by patient-related and ICU setting-related variables. Thus, no single optimal blood glucose target range for ICU patients can be advocated. It appears safe not to embark on targeting 'age-normal' levels in PICUs that are not equipped to accurately and frequently measure blood glucose, and have not acquired extensive experience with IV insulin administration using a customized guideline. A simple fallback position could be to control blood glucose levels as close to normal as possible without evoking unacceptable blood glucose fluctuations, hypoglycemia, and hypokalemia."

A review of hyperglycemia in the preterm infant¹¹⁴ suggested the following pragmatic approach to management: confirm hyperglycemia with laboratory testing; treat any underlying problem such as sepsis, stress, etc.; calculate glucose infusion rates, and if greater than 12 mg/kg/min, then reduce infusion rate; treat with insulin if glucose level is more than 10 mmol/L (or other symptoms such as polyuria exist), but start cautiously with very low doses; and, finally, if hyperglycemia persists, consider other diagnoses such as diabetes. A similar approach in older children may still be appropriate, particularly if there are

limited facilities for frequent and accurate monitoring of glucose levels.

Diabetes Mellitus

The incidence of insulin-dependent diabetes mellitus has been increasing across the world,¹¹⁵ and even in countries with highly developed healthcare services, children with diabetes mellitus have a higher mortality than those without^{116,117}; standardized mortality ratios of 2.15¹¹⁸ to 4.2 have been reported,¹¹⁹ although some deaths are not directly related to diabetes. The highest mortality is in children aged 1 to 4 years, in whom the standardized mortality ratios may be much higher. Most deaths attributable to diabetes mellitus occur as a consequence of DKA or hyperglycemia, with the remainder attributable to hypoglycemia.¹²⁰ DKA is relatively common at the time of first presentation and particularly in younger children¹²¹ where the diagnosis may be delayed. The recent mortality rates in the developed world for DKA have ranged from 0.15% to 0.31%¹²² but may be far higher in other settings.^{123,124} The most common cause of death among patients with DKA is cerebral edema. Other causes of death in DKA include electrolyte disturbances, hypoglycemia, pulmonary edema, rhabdomyolysis, infections (including mucormycosis), and thrombosis.¹¹⁵ The management of DKA in childhood has been reviewed elsewhere.¹²⁵

There has also been a marked increase in the incidence of type 2 (or non-insulin-dependent) diabetes mellitus,^{126,127} particularly in association with obesity. Patients with this condition may also present to the PICU with life-threatening hyperglycemic hyperosmolar syndrome.

Cerebral Edema in Diabetic Ketoacidosis

In affluent countries, overt symptomatic cerebral edema occurs in 0.5% to 1% of pediatric DKA episodes¹²⁵ with risks being higher in young children and previously undiagnosed diabetics. Mortality is high (21 to 24%), and 15 to 26% of survivors will have permanent morbidity (including pituitary insufficiency).¹²⁵ However, a much higher proportion of children with DKA will have an altered level of consciousness on presentation, often with features of cerebral edema evident on magnetic resonance imaging (MRI).¹²⁸

The exact mechanisms of cerebral edema in DKA are not clear,¹²⁹ although some studies suggest that it may be related to vasogenic factors rather than osmotic factors.¹³⁰ Cerebral ischemia and reperfusion injury have also been considered.¹³¹

Cerebral hyperemia has also been demonstrated soon after initiation of therapy for DKA.¹³² At the time of presentation, the following features have been associated with increased risk of cerebral edema: younger age, relatively low PCO_2 , high serum urea, and more severe acidosis.^{125,133} Aspects of treatment that have been associated with increased risk include higher volumes of fluid administration during the first 4 hours of resuscitation, administration of insulin during the first hour of therapy, the administration of bicarbonate, and either a slow increase in serum sodium or a fall in glucose-corrected sodium during therapy.^{133,134} Most of these data are epidemiologic, and there are no randomized controlled studies showing that different treatment strategies addressing these issues have reduced cerebral edema.¹³⁵ Such studies are currently planned.¹³⁶

Cerebral edema may be present before therapy for DKA in 5% of cases, although most cases develop 4 to 12 hours after the initiation of therapy.¹³⁷ The clinical signs of cerebral edema in DKA are variable and include headache, deterioration in level of consciousness, inappropriate slowing of pulse rate, and increased blood pressure. However, children with no clinical signs of cerebral edema can have brain swelling,¹²⁸ and a significant proportion of children have disrupted memory function following episodes of DKA.¹³⁸ Adverse outcomes following cerebral edema have been associated with greater neurologic depression at the time of diagnosis, high initial serum urea nitrogen,^{137,139} and intubation with hyperventilation to a PCO_2 of less than 22 mm Hg.¹³⁹

Although the biochemical derangements of hyperglycemia, metabolic acidosis with ketosis, and electrolyte abnormalities are the most obvious problems in DKA, significant derangements in other systems have been seen, including plasma tryptophan levels,¹⁴⁰ thiamine levels,¹⁴¹ cytokine¹⁴² and lymphocyte responses,¹⁴² and coagulation abnormalities. There is little doubt that DKA is associated with a thrombotic state¹⁴³ and an increased incidence of cerebrovascular accidents. Care should be taken in the use of femoral central venous access as this may have a higher than usual complication rate in these patients.¹⁴⁴ A reported case of myocardial infarction related to DKA¹⁴⁵ may be a complication of the thrombotic state. Although myocardial function is generally normal in DKA, myocarditis¹⁴⁶ has been noted in occasional case reports, and pulmonary edema may be more common than previously recognized.¹⁴⁷ Prolongation of the QTc interval may be common in DKA (it correlates with ketosis), and careful cardiac monitoring is essential.¹⁴⁸

Principles of Management. Management of DKA should be coordinated by an experienced diabetes team using guidelines such as the recently published consensus statement,¹²⁵ which is shown in Figure 151-2.

The biochemical criteria for the diagnosis of DKA include a serum glucose concentration higher than 11 mmol/L (approximately 200 mg/dL), ketonemia and ketonuria, and acidosis with venous pH less than 7.3, or serum bicarbonate level less than 15 mEq/L.¹²⁵ The severity of DKA is defined by the level of acidosis, with mild having venous pH less than 7.3 (or bicarbonate level <15 mmol/L), moderate pH less than 7.2 (or bicarbonate level <10 mmol/L), and severe pH less than 7.1 (or bicarbonate level <5 mmol/L).¹²⁵ Children with severe DKA should be managed in a specialized diabetic unit or in the PICU.

Baseline Assessment. An admission weight should be obtained if at all possible, and future therapy should be based on this weight. Blood samples should be taken for the following: serum or plasma glucose, electrolytes (including bicarbonate or total carbon dioxide), blood urea nitrogen, creatinine, osmolality, venous (or arterial in critically ill patients) pH, PCO_2 , calcium, phosphorus, and magnesium concentrations (if possible), HbA1c, and hemoglobin and hematocrit or complete blood count. Measurement of blood β -hydroxybutyrate concentration, if available, is useful to confirm ketoacidosis and may be used to monitor the response to treatment.¹⁴⁹⁻¹⁵³ Urine specimens should be analyzed for ketones, although these may be poorly reflective of serum ketones. Electrocardiograms may be useful if delays are expected in getting potassium results.

Fluid Management. The objectives of fluid and electrolyte replacement therapy are restoration of circulating volume, replacement of sodium and body fluid deficit, improved renal function with enhanced clearance of glucose and ketones from the blood, and minimization of the risk of cerebral edema. There is a wide range in the amount and rate of fluid and electrolyte loss in patients presenting with DKA (depending on the rate of onset and duration of symptoms, the severity of vomiting or diarrhea or both, and the fluid ingested by the patient). There is similarly a wide range of intravascular status ranging from normovolemia to severe hypovolemia (uncommon). Clinical assessment of dehydration is inaccurate,^{154,155} and there is an unpredictable rate of ongoing fluid loss related to the osmotic diuresis. In the (unusual) presence of hypovolemic shock, it may be reasonable to infuse 0.9% saline using aliquots of 5 to 10 mL/kg until an acceptable blood pressure is obtained. Typically, 10 to 20 mL/kg needs to be infused over 1 to 2 hours. Ringer's lactate may be a reasonable alternative because administration of large volumes of 0.9% saline has been associated with the development of hyperchloremic acidosis. There is no evidence to support the use of colloid solutions.

Thereafter, the acceptable principles are that hypovolemia, rapid changes in plasma osmolality, and large volumes of sodium uptake should be avoided. Fluid therapy should be calculated to achieve rehydration over 48 hours. Careful monitoring of fluid balance is essential to ensure that patients are neither losing excessive fluid (via osmotic diuresis) nor gaining excessive fluid. Fluid with a tonicity less than that of 0.45% saline should not be used.

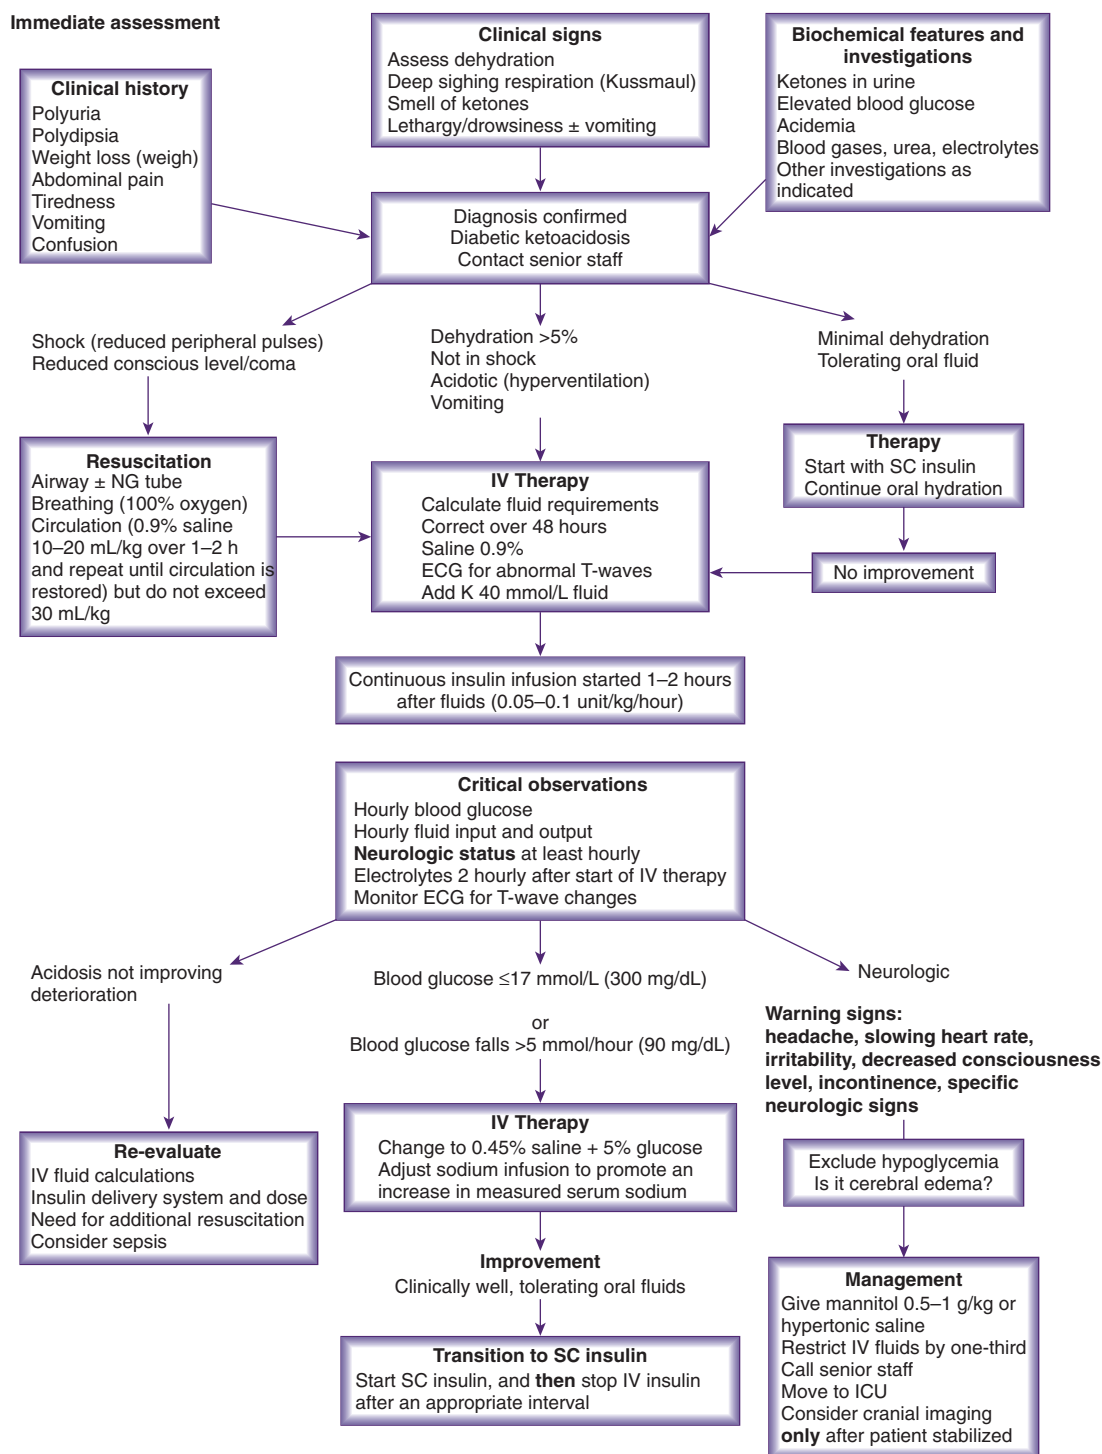

FIGURE 151-2 ■ ISPAD clinical practice guidelines management algorithm for the treatment of diabetic ketoacidosis. (From Wolfsdorf JI, Allgrove J, Craig ME, et al. ISPAD Clinical Practice Consensus Guidelines 2014. Diabetic ketoacidosis and hyperglycemic hyperosmolar state. *Pediatr Diabetes* 2014;15:154–179.)

Despite the fact that almost all patients with DKA are potassium depleted, serum potassium levels frequently are increased at presentation. With initiation of insulin therapy and correction of acidosis, there is rapid intracellular movement of potassium, and careful monitoring of potassium levels is essential. As soon as potassium levels are less than 5.5 mEq/L, 30 to 40 mEq/L of potassium should be added to the

fluid infusions, and 0.5 to 1 mEq/kg/h of potassium may be required to correct potassium deficits. Potassium may be given as chloride or phosphate. Although severe hypophosphatemia is common,¹⁵⁶ and symptomatic hypophosphatemia has been reported,¹⁵⁷ there is no evidence that phosphate administration is routinely necessary in the management of DKA, and the clinical effects of severe hypophosphatemia

are rare in DKA. Theoretically, phosphate administration may reduce insulin resistance and depletion of adenosine triphosphate and have positive effects on 2,3-diphosphoglycerate. Administration of potassium phosphate helps to decrease the chloride load given to patients with DKA and may be used safely, provided that calcium levels are monitored carefully.¹⁵⁸ Glucose must be added to the infusion of fluids when the glucose levels are 14 to 17 mmol/L to avoid hypoglycemia.

Bicarbonate. There is lack of evidence for benefit from the administration of bicarbonate to patients with DKA, and significant complications are documented (particularly in children).¹⁵⁹ Bicarbonate should not be given routinely, not in bolus form, and possibly only in patients who have a pH less than 6.9 despite appropriate correction of intravascular volume and adequate insulin therapy.

Insulin Therapy. Current guidelines recommend that insulin should be provided as a continuous low-dose infusion starting at 0.1 U/kg/h, approximately 1 to 2 hours after starting fluid replacement. However, there is recent evidence that ultra-low-dose insulin at 0.05 U/kg/h may be at least equivalent to the higher dose.¹⁶⁰ If there is no response to insulin therapy, the infusion should be reviewed for technical problems (incorrect preparation, adhesion of insulin to infusion tubing), and the patient should be reviewed for ongoing hypovolemia or uncontrolled sepsis. There is no place for a bolus of IV insulin or an initial loading dose, other than in the management of life-threatening hyperkalemia. The insulin infusion should be continued until ketoacidosis is resolved and the patient is fully conscious and retaining solid food.

Treat Underlying Cause. In previously undiagnosed patients, the cause of DKA is insulin deficiency. Even in previously diagnosed patients, most episodes of DKA probably are related to insulin omission or treatment error, although children 3 years old or younger are more likely to have a bacterial infection.¹⁶¹ If infection is suspected as the precipitating cause of DKA, aggressive therapy with antibiotics and drainage of any abscess should be instituted. Routine prophylactic antibiotic therapy is not indicated in DKA.

Monitoring. Although some patients are hypovolemic on presentation, there is little evidence that invasive hemodynamic monitoring is necessary. Careful monitoring of sodium levels is essential because smaller changes in serum sodium with therapy are associated with the development of cerebral edema.¹³⁷ Hyperlipidemia may decrease the aqueous phase of serum and artificially reduce sodium levels; this can be corrected using the following formula¹⁶²:

$$\text{True sodium (mEq/L)} = \text{reported sodium (mEq/L)} \\ \times (0.021 \times \text{triglycerides [mg/dL]} + 0.994)$$

The osmotic load of glucose also decreases serum sodium levels, with a decrease in sodium level of approximately 1.6 to 1.8 mEq/L per 100 mg/dL increase in glucose¹⁶³ (alternatively, Corrected sodium = measured Na + 2([plasma glucose – 5.6]/5.6) (mmol/L). The expectation is that with decreasing levels of hyperglycemia and hyperlipidemia, sodium levels should increase. This may be offset, however, by urinary losses of sodium secondary to osmotic diuresis. Careful and frequent monitoring of potassium and glucose levels is essential. If phosphate is being given, calcium levels should be monitored. Regular acid-base monitoring is required.

Monitoring of end-tidal PCO₂¹⁶⁴ or transcutaneous PCO₂¹⁶⁵ could be used as a noninvasive method for continuous monitoring of response to therapy for DKA. The only proviso¹⁶⁶ is that any changes in respiratory drive or efficiency of the respiratory system may mask changes in acid-base that otherwise might be reflected by capnometry.

Investigations for Possible Cerebral Edema in DKA. Although cerebral edema is the most common cause of depressed level of consciousness in DKA, there are other causes that are amenable to therapy, including cerebral venous thrombosis¹⁶⁷ and acute hydrocephalus.¹⁶⁸ Other abnormalities, such as brain infarction¹⁶⁹ and extrapontine myelinolysis,¹⁷⁰ have been seen. Computed tomography

(CT) of patients with a depressed level of consciousness may be recommended to exclude other treatable pathology. Because the risks are relatively low, however, excluding other pathology must be balanced against the risks associated with moving ill patients to the radiology suite.

Mannitol has been used for the management of cerebral edema¹⁷¹ (0.25 to 1 g/kg over 20 minutes), although there are no controlled studies. Hypertonic saline (5 to 10 mL/kg of 3% saline) may be an alternative¹⁷²; however, a recent retrospective review suggested that outcomes were worse after hypertonic saline than after mannitol¹⁷³ despite a general increase in the use of hypertonic saline in the United States for this indication. It is possible that cerebral edema in DKA is vasogenic in origin, in which case there may be different roles for mannitol and hypertonic saline.¹³⁰ Hyperventilation after intubation for cerebral edema may be associated with worse outcomes.¹³⁹

Summary. Despite improvements in the management of DKA, it remains a serious illness with significant morbidity and mortality. In addition to improving management of the condition, strong focus must be brought to ensure that the condition is avoided when possible and diagnosed and treated promptly when it occurs.

Thyroid Insufficiency

Neonates¹⁷⁴ and particularly preterm infants^{175,176} exposed to large amounts of iodine in iodine-containing antiseptics or via iodinated contrast media¹⁷⁷ may develop transient hypothyroidism (also called the *Wolff-Chaikoff effect*) as a result of absorption of iodine. This has also been shown in infants undergoing cardiac catheterization and cardiac surgery,¹⁷⁸ particularly following wound irrigation with povidone iodine solutions.¹⁷⁹ Care should be taken to limit the exposure of infants to iodine-containing agents. Triiodothyronine supplementation may be considered in children who have been exposed to significant amounts of iodine before or during a critical illness.

The sick euthyroid syndrome is well documented in the PICU,¹⁸⁰ particularly in patients undergoing cardiac surgery.¹⁸¹ Although there may be benefit to some children, there is no established role for triiodothyronine supplementation after cardiac surgery.¹⁸¹ Additionally, children with Down syndrome have a high incidence of hypothyroidism, both congenital and acquired.¹⁸² Attention should be paid to the possible need for triiodothyronine supplementation in critically ill children with Down syndrome.

METABOLIC CRISES

Epidemiology

IEM are a heterogeneous group of conditions that are characterized by defects in metabolic pathways that result in abnormal metabolism and/or the accumulation of toxic metabolites.¹⁸³ There is a vast range of IEM, with an ever increasing list of conditions. Population data on IEM suggest a minimal incidence of 35 to 40 per 100,000 live births.¹⁸⁴⁻¹⁸⁶ IEM have a diverse presentation and are part of the differential diagnosis of many children admitted to the PICU with acute illness. In the 1960s, newborn screening programs using dried blood spots to identify conditions such as phenylketonuria were initiated in parts of the United States.¹⁸⁷ The advent of techniques such as tandem mass spectrometry has made it possible to screen for a wide range of conditions (including fatty acid oxidation defects, organic acidemias, and amino acidopathies), and this has become the norm for screening programs in many parts of the world. More recently, the American College of Genetics provided guidelines on suitability of a condition to be included in newborn screening programs, including concerns such as whether the condition can be detected within 24 to 48 hours of birth, whether the screening test is specific and sensitive, and whether the condition is amenable to treatment if detected early.¹⁸⁸ A consequence of these screening programs is that in many parts of the world there are less likely to be PICU admissions with undiagnosed IEM, but there may be increased numbers of admissions of children with known IEM.

Although there are a bewildering number of IEM, many are amenable to therapy. Patients with incurable conditions may derive considerable relief of suffering from diagnosis and appropriate therapy. Even when a condition is not amenable to therapy, it is important to make a diagnosis to facilitate counseling for the family involved and prevent unnecessary suffering in future children. Long-term management of most IEM requires a team approach, including metabolic experts, dietitians, geneticists, biochemists, and social workers, to elucidate the exact nature of the problem, provide appropriate therapy and therapeutic plans, and give genetic and family counseling. Although screening tests for IEM can be done in most diagnostic laboratories, the specialized tests required to identify the exact nature of an IEM can be done at relatively few laboratories. Despite the complexity of IEM, there are principles that apply to the management of all children who are admitted to a PICU (see [Table 151-1](#)).

When to Consider an Inborn Error of Metabolism in the Pediatric Intensive Care Unit

IEM may be classified into four diagnostically useful groups: (1) disorders that give rise to intoxication (e.g., organic acidemias and urea cycle defects), (2) disorders involving energy metabolism (e.g., fatty acid oxidation defects and respiratory chain defects), (3) disorders involving complex molecules in which symptoms are permanent, progressive, and independent of intercurrent events (e.g., peroxisomal disorders, lysosomal disorders, and congenital defects of glycosylation), and (4) those disorders that present with seizures (particularly in the neonatal period). The conditions most likely to present acutely in the PICU are conditions involving intoxication and energy metabolism. There is overlap, however, between these groups in terms of presentation. There may also be variation in the presentation of conditions that have the same underlying genetic abnormality.

Although the clinical features of an IEM may be related primarily to the accumulation of a toxic metabolite, the condition may be complicated by the relative deficiency of another compound or increased stress put on other metabolic pathways by the primary problem. Management may involve limiting the intake of potentially toxic substances, increasing the removal of toxic substances, supplementation of deficient substances, and supplementation of other metabolic pathways that are being stressed.

IEM should be considered as part of the differential diagnosis of any child or infant who presents with a severe illness, particularly during the neonatal period.¹⁸⁹ Acute symptoms that are associated with IEM include encephalopathy (acute or acute on chronic), intractable seizures, hepatic failure, cardiomyopathy, metabolic acidosis, and hypoglycemia ([Table 151-3](#)). Family history of SIDS or prior childhood deaths may suggest IEM. Particular attention should be paid to the identification of particular risk factors for the differential diagnoses, including drug exposure, prolonged rupture of membranes, and perinatal asphyxia.

Specific Clinical Presentations

Intractable Seizures

Seizures (in isolation) are an uncommon presentation of IEM and, with the exception of the pyridoxine-dependent seizures, tend to be associated with other clinical and metabolic abnormalities. In neonates or some infants presenting with intractable seizures, pyridoxine-dependent seizures (PDS),¹⁹⁰ pyridoxine phosphate oxidase deficiency (PNPO), hypophosphatasia, and folinic acid-responsive seizures¹⁹¹ should be considered. The clinical diagnosis of PDS and PNPO depends on demonstration that seizure control is dependent on continuous pharmacologic doses of pyridoxine or pyridoxal-5'-phosphate, respectively. There is a range in clinical presentation, and PDS should be considered in any infant up to age 18 months presenting with seizures.

Patients with defects in the transport of glucose across the blood-brain barrier associated with mutations in the *GLUT1* gene may

TABLE 151-3

Factors That Should Alert the Intensivist to the Possibility of an Inborn Error of Metabolism

HISTORY

General

Population group with high incidence of inborn errors of metabolism (IEM)
 Consanguinity of parents
 Previous history of apparent SIDS or childhood deaths in the family
 Presence of dysmorphic features associated with inborn error of metabolism
 Previous history multiple spontaneous abortions
 Hyperemesis may be associated with fat oxidation disorders,²⁴⁰ as may frank hepatic symptoms such as acute fatty liver of pregnancy or the more severe HELLP syndrome (hemolysis, liver enzymes, low platelets).
 Deterioration after apparently being normal at birth, particularly if Apgar scores and early neonatal period were normal
 Earliest signs of IEM in the neonatal period may include lethargy and poor feeding, which may progress rapidly to obvious depressed level of consciousness.
 Depressed level of consciousness without obvious explanation
 Vomiting is an unusual clinical feature of illness in neonates and is strongly associated with IEM.
 Strange odors
 Previous history of being "sickly" with episodes of intermittent vomiting
 Previous hospital admissions (even for apparent respiratory symptoms as this may be acidosis)
 Unusual dietary preferences by the child
 Onset of virtually any organ dysfunction (liver, heart, renal, etc.) may be related to inborn error.

In childhood

EXAMINATION

General

In neonatal period

Dysmorphic features that may be associated with IEM
 Strange odors
 Neurologic signs in IEM tend to include increased tone and abnormal movements, in contrast to the features of sepsis, which usually is associated with decreased tone.
 Acute or intermittent ataxia is a common feature of IEM.

In childhood

IEM, inborn errors of metabolism; SIDS, sudden infant death syndrome.

present with seizures. Often the only clue is the presence of low cerebrospinal fluid (CSF) glucose in the presence of normal blood glucose. Patients may improve on a ketogenic diet.¹⁹²

IEM that may present with seizures associated with lactic acidosis include biotinidase deficiency, disorders of mitochondrial energy metabolism (including pyruvate dehydrogenase deficiency and mitochondrial electron transport chain defects), and peroxisomal and storage disorders.

Biotinidase deficiency (an autosomal recessively inherited disorder of biotin recycling) can be ameliorated or prevented by administering pharmacologic doses of the vitamin biotin.¹⁹³ A large proportion of cases present with seizures and hypotonia, associated with failure to thrive and skin rash or alopecia. Some 50% of cases have ataxia, developmental delay, and eye problems (conjunctivitis and optic atrophy), with more than 75% developing hearing loss. There is a considerable variation in presentation,¹⁹⁴ with features ranging from mild episodes of seizure and ataxia to severe metabolic failure and death. Onset of symptoms may occur at any time from the neonatal period through to adulthood. Untreated individuals may have

ketoacidosis, lactic acidosis, and/or hyperammonemia with a range of other metabolic anomalies.¹⁹⁴ Diagnosis can be made from analysis of organic acids in urine, whereas an enzyme assay can be done on blood. Guidelines for testing have recently been published.¹⁹⁴

Intractable tonic-clonic seizures may also be a feature of molybdenum cofactor deficiency.¹⁹⁵ This presents in early infancy with seizures, encephalopathy in the absence of metabolic acidosis, hypoglycemia or hyperammonemia, and failure to thrive. Clinical features, CT findings, and neuropathology may be similar to that seen in severe hypoxic-ischemic brain injury with initial cerebral edema progressing to atrophy. However, there may be typical imaging findings.¹⁹⁶ Intraocular lens dislocation may be a clinical feature.¹⁹⁷ Uric acid levels are low, whereas urinary amino acid analysis shows increased S-sulfocysteine. Sulfite may be demonstrated on fresh urine specimens. Electrospray tandem mass spectrometry of urine or urine-soaked filter paper may facilitate rapid diagnosis.

Seizures may be part of the clinical presentation of many other disorders, including seizures with lactic acidosis (Leigh disease, mitochondrial encephalopathy lactic acidosis, and stroke-like episodes [MELAS]), mitochondrial encephalopathy with ragged red fibers [MERRF]), GM₂ gangliosidosis, and peroxisomal disorders. Other clinical features predominate in these conditions and should direct investigation.

Investigation and Management. In infants presenting primarily with intractable seizures, investigations should include measurement of blood glucose, blood acid-base status, blood lactic acid (in association with pyruvate levels), CSF glucose, lactic acid and pyruvic acid levels, urinary organic acids, and sulfite. CT and MRI help to diagnose disorders of abnormal accumulation of metabolites and exclude structural brain problems that are responsible for symptoms. Treatment focuses on control of the airway and respiration together with control of seizures. Pyridoxine or biotin should be administered early in appropriate doses if indicated.

Encephalopathy

The onset of acute encephalopathy always constitutes a medical emergency, and the cause must be elucidated as rapidly as possible. The differential diagnosis includes trauma, infection, intracranial space-occupying lesions, toxin ingestion, acute hepatic failure or Reye syndrome, intracranial vascular problems (thrombosis, hemorrhage, or embolic phenomena), and seizure disorders. There is often a strong tendency to attribute neurologic symptoms to hypoglycemia or hypocalcemia, but because these may be associated with IEM, it is vital that IEM be considered as part of the cause of the hypoglycemia. The IEM that present with acute encephalopathy vary with age. In the neonatal period, the common IEM include urea cycle defects (with hyperammonemia), maple syrup urine disease, nonketotic hyperglycinemia, and organic acidopathies.¹⁹⁸ All of these, with the exception of nonketotic hyperglycinemia, may also present during childhood. During childhood, the common IEM presenting with acute encephalopathy include fatty acid oxidation defects and maple syrup urine disease.

Investigation. The specimens collected for diagnosis of sepsis should be collected, including blood culture, hemoglobin, white blood cell count (with differential), and platelets. Serum electrolytes should be checked, including sodium, potassium, calcium, phosphate, and magnesium. Liver function tests are essential because acute hepatic failure may cause acute encephalopathy, and the liver may be affected by IEM. Specimens for testing for IEM must be collected at the time of presentation because this may provide the best opportunity for diagnosis (Table 151-4).

Blood Glucose Levels. The reader is referred to the earlier discussion of the approach to hypoglycemia. Hypoglycemia may be a particular feature of fatty acid oxidation defects and organic acidurias. Immediate correction of hypoglycemia is essential.

Plasma Ammonia Levels. Plasma ammonia levels should be checked in all children, particularly neonates, with unexplained depressed level of consciousness, particularly if there is hypotonia and

apnea (see section on hyperammonemia for management and investigation). Treatment of severe hyperammonemia is an emergency.

Liver Function Tests. Reye syndrome is part of the differential diagnosis of acute encephalopathy, but fatty acid oxidation defects, such as medium-chain acyl-CoA dehydrogenase deficiency, carnitine deficiency (usually with associated myopathy), and, far less frequently, long-chain acyl-CoA dehydrogenase deficiency and short-chain acyl-CoA dehydrogenase deficiency, may present with encephalopathy (usually in the neonatal period).

Blood Gas Analysis. Arterial blood gas analysis should be performed with particular attention to the presence of metabolic acidosis and calculation of the anion gap.¹⁹⁹

Blood Lactate Levels. Blood lactate levels may be increased in many situations but typically are very elevated in mitochondrial electron transport chain defects.

Plasma Carnitine. Carnitine levels may be substantially decreased in organic acidurias and fatty acid oxidation defects. Analysis of acyl carnitine and amino acid profile may help make the diagnosis of isovaleric aciduria, methylmalonic aciduria, and propionic acidemia.

Quantitative Amino Acid Analysis. Quantitative amino acid analysis is necessary to identify the aminoacidopathies. Screening tests on the urine may point in the direction of certain conditions.

Urinary and Blood Ketones. Ketones are unusual in the neonatal period but tend to be a feature of maple syrup urine disease and propionic, isovaleric, and methylmalonic acidemia. Quantitative determination of blood ketones (acetoacetate using urine ketone strips or β -hydroxybutyrate by specific blood strip) may be a useful bedside screen.

Urinary Organic Acids. Urinary organic acids are abnormal in maple syrup urine disease, organic aciduria, and fatty acid oxidation defects.

Management. The principles of therapy are as follows:

1. Maintain airway control and breathing.
2. Maintain circulation.
3. Treat underlying or associated sepsis.
4. Remove toxic compounds.
5. Ensure an appropriate energy source.
6. Provide any specific therapy that is available.

The toxic compounds that potentially can be removed include ammonia and leucine (see below).

Specific Conditions

Maple Syrup Urine Disease (MSUD). If there is no acidosis and the ammonia is not increased, MSUD should be considered. Patients typically are not dehydrated, are not acidotic, have no hyperammonemia, and have no hematologic abnormalities. Cerebral edema is a feature of MSUD within the neonatal period and during later presentations. The urine may smell like maple syrup, but the smell is also similar to that of burned sugar.¹⁹⁸ The urine smell may be difficult to detect in the first few days of life and then may be detected on diapers that have been allowed to dry.²⁰⁰ Urine tests for ketones are usually strongly positive, and dinitrophenylhydrazine is usually positive, although both tests may be negative before 3 days of age.²⁰⁰ Tandem mass spectrometry is the most efficient screening test in neonates. Leucine levels can be checked rapidly on whole-blood filter paper specimens, or quantitative amino acid analysis should be done on plasma or serum. Principles of management have been to remove leucine using dialysis and to reduce the production of leucine by dietary manipulation. Hemodialysis decreases leucine levels rapidly,²⁰¹ particularly if used with dietary therapy, but peritoneal dialysis may be effective if hemodialysis is not available.²⁰² Previously, exchange transfusion, peritoneal dialysis, and hemofiltration were reported to decrease leucine levels. Morton and colleagues²⁰⁰ have used a protocol consisting of total caloric intake of 120 to 140 kcal/kg/day with lipid forming 40% to 50% of calories, 3 to 4 g/kg/day of protein as essential and nonessential amino acids with 80 to 120 mg/kg/day each of isoleucine and valine, and 250 mg/kg/day each of glutamine and alanine, with tyrosine, histidine, and threonine supplemented to normalize plasma amino acid ratios; careful attention should be paid to sodium

TABLE 151-4 Specimen Collection for Inborn Errors of Metabolism

| SUBSTANCE | TESTS | COMMENTS ON TECHNIQUE | CONDITIONS IDENTIFIED |
|---|--|--|--|
| Urine | Detecting odors | Urine odors are best identified from urine drying on filter papers or from urine that has been kept in a closed container at room temperature for a while. | MSUD (smell of maple syrup; some describe this as burned sugar ¹³³) Isovaleric acidemia (sweaty feet odor) 3-methylcrotonyl glycinuria (catlike) |
| Urine screening tests | Ketones | | Urinary ketones are rare in neonates and are almost diagnostic of an inborn error of metabolism in a neonate. |
| | Dinitrophenylhydrazine | | Strongly positive with MSUD, PKU, or in ketoacidosis |
| | Ferric chloride | | Green color with PKU; other colors may occur with other conditions |
| | Merckoquant 10013 Sulfite test | Urine specimen must be fresh because sulfite oxidizes rapidly at room temperature | Molybdenum cofactor deficiency |
| | Reducing substances | | Galactosemia |
| Urine | Measurement of organic acids and amino acids | Specimen collected and frozen at -20°C acidurias | All aminoacidemias and organic acidurias |
| | Measurement of acyl carnitines and acyl glycines | Can increase the sensitivity of these tests by the use of loading dose of levocarnitine, 100 mg/kg orally | Many fatty acid oxidation defects |
| Blood | Anion gap | Correct for hypoalbuminemia | Screen to identify generally unmeasured anions. |
| | Tandem mass spectrometry | Collected as blood on filter paper | All fatty acid oxidation defects, many of the aminoacidemias |
| | Galactose-1-phosphate uridylyltransferase | Collected as blood on filter paper | Abnormalities of the carnitine pathways |
| | Estimation of ammonia, lactate, pyruvate, and ketoacids | All of these substances may be unstable; must collect on ice and transport immediately to laboratory. | Galactosemia |
| | Genetic studies | Before blood transfusion | Aminoacidopathies, urea cycle defects |
| Skin, liver, muscle, and endocardial biopsy | Fibroblast culture, enzyme identification, identification of abnormal collections and organelles | | All problems with identified genetic abnormalities Enzyme defects, organelle defects |

MSUD, maple syrup urine disease; PKU, phenylketonuria.

balance to ensure that serum sodium is kept at greater than 140 mEq/L. Hyperosmolar therapy is initiated if cerebral edema develops. This protocol produces decreases in leucine equal to that seen after dialysis. Recent studies suggest that norleucine may have a role in reducing brain injury in patients with MSUD.²⁰³

Isovaleric Aciduria, Methylmalonic Aciduria, and Propionic Acidemia. Isovaleric aciduria, methylmalonic aciduria (MMA), and propionic acidemia may present in the neonatal period with encephalopathy hyperammonemia, ketoacidosis (occasionally hyperammonemia may induce a respiratory alkalosis), moderate lactic acidosis, and hypocalcemia. The smell associated with isovaleric aciduria may be distinctive (commonly described as resembling “sweaty feet”). Blood glucose levels may be variable from hypoglycemia to hyperglycemia. Dehydration is a feature of the clinical presentation, partly related to vomiting and poor intake and partly related to poor renal concentrating ability. One-third of patients may present later in life. Stroke-like episodes are a feature of isovaleric aciduria, MMA, and propionic acidemia in later life, although there may be a range of neurologic presentations, including hypotonia and developmental delay. Extrapyramidal signs related to infarction of the basal ganglia may be a feature of MMA and propionic acidemia. Neutropenia, thrombocytopenia, and anemia are common in the neonatal presentation, whereas neutropenia may also be a feature of a later presentation. Sepsis may be a significant component of clinical exacerbations, particularly in propionic acidemia. Pancreatitis has been reported to be associated with these disorders. Cardiomyopathy may also develop, particularly during decompensation. Isovaleric aciduria, propionic acidemia, and

MMA aciduria are diagnosed by the organic acid profiles, and tandem mass spectroscopy may be useful by looking at the acyl carnitine profiles.

Patients presenting in the neonatal period with encephalopathy require treatment with limitation of protein intake (this requires varied adjustment to a diet with appropriate amino acid profile), removal of toxins (exchange transfusion may be useful; MMA can be cleared renally if adequate fluid volumes are given), ensuring normal glucose levels, promoting anabolism, and management of sepsis. Some patients with MMA may respond to therapy with hydroxycobalamin, and this should be given for several days to assess response. Supplemental glycine should be given to patients with isovaleric aciduria, and carnitine supplementation is useful for all. Some patients with propionic acidemia may benefit from metronidazole to decrease propionate metabolites from the bowel.

Nonketotic Hyperglycinemia. Nonketotic hyperglycinemia presents in early infancy with severe encephalopathy in the absence of acidosis, ketosis, hypoglycemia, hyperammonemia, or any other clinical abnormalities. Although the outcome is almost invariably poor, there have been more recent descriptions of transient neonatal hyperglycinemia.²⁰⁴ There is an association of abnormality of the corpus callosum with nonketotic hyperglycinemia.²⁰⁵ The outcomes of patients with nonketotic hyperglycinemia have been recently reviewed.²⁰⁶

Hypoglycemia

The reader is referred to the section on endocrine crises for an approach to hypoglycemia. In hyperinsulinemia, the hypoglycemia

typically develops soon after a feed, whereas patients with defects in fatty acid oxidation tend to be able to tolerate fasts of 4 to 8 hours. In hyperinsulinemia, it often is difficult to provide adequate amounts of glucose to correct the hypoglycemia (may require >12 mg/kg/min together with glucagon). In defects of gluconeogenesis, the hypoglycemia is relatively easy to control but usually does not respond to glucagon administration. In hereditary fructose intolerance, the onset of hypoglycemia is concurrent with the introduction of sucrose (source of fructose) into the diet. Although hypoglycemia may occur in association with sepsis, many IEM are associated with sepsis (e.g., direct association with *Escherichia coli* and galactosemia, sepsis as a precipitant of crisis, or ill health from IEM causing increased risk of sepsis) and should be considered diagnostically even if sepsis is proven.

Investigation and Management. If the glucose level is low, a venous specimen of blood should be collected immediately for laboratory glucose estimation. The clinician should give 0.5 g/kg of 10% to 25% dextrose in water (diluted with water for injection) promptly as an IV bolus followed by administration of 4 to 8 mg/kg/min of glucose. The glucose level should be reviewed within 30 minutes. The rate of glucose infusion may need to be increased, and high requirements suggest hyperinsulinemia.

Urine for Reducing Substances. If this test is positive, glucose should be excluded, but in the setting of hypoglycemia this is unlikely unless there have been substantial doses of glucose given. If reducing substances are positive, this suggests galactosemia, hereditary fructosemia, or tyrosinemia.

Urinary Ketones. If urinary ketones are positive, the clinician should assess for urinary and plasma organic acids and quantitative amino acids. High urinary ketones in the presence of hepatomegaly suggest glycogen storage disease type 1, fructose-1,6-diphosphatase (FDPase) deficiency, or β -ketothiolase deficiency.²⁰⁷ In β -ketothiolase deficiency, lactate levels are normal, whereas they are increased in glycogen storage disease type 1 and FDPase deficiency. In the absence of hepatomegaly, high ketones suggest ketotic hypoglycemia or deficiencies of growth hormone or glucocorticoids.

Plasma Free Fatty Acids. If plasma free fatty acids are elevated, the patient is likely to have a fatty acid oxidation defect, but if they are low, hyperinsulinemia is more likely.

Lactate Levels. Lactic acidosis in association with hypoglycemia is characteristic of defects of gluconeogenesis, such as glycogen storage diseases.

Urinary Organic Acids, Plasma Amino Acids, and Ammonia Levels. Urinary organic acids, plasma amino acids, and ammonia levels should be measured as hypoglycemia may be a feature of abnormalities of all these compounds.

Specific Conditions

Galactosemia. Please see the section on hepatitis. Hypoglycemia may be a prominent feature of galactosemia, whereas hepatitis may be a more common presentation.

Hereditary Fructose Intolerance. Hereditary fructose intolerance is characterized by the onset of severe vomiting and hypoglycemia after the ingestion of fructose or sucrose.

Glycogen Storage Disease Type 1. Glycogen storage disease type 1 may present in the neonatal period with hypoglycemia that may be mild or easily controlled. However, patients present later with hepatomegaly and lactic acidosis. The hypoglycemia does not respond to therapy with glucagon.

Fatty Acid Oxidation Defects. Defects in the mitochondrial oxidation of free fatty acids result in the accumulation of fatty acid oxidation products, which may produce encephalopathy, hepatocellular dysfunction, and cardiac arrhythmias, which are a potentially fatal complication of fatty acid oxidation defects. Defects in fatty acid oxidation may also result in failure to meet the energy requirements of tissues such as skeletal muscles or cardiac muscles, resulting in myopathy or cardiomyopathy. Many studies have suggested that fatty acid oxidation defects may be an important cause of SIDS and are an important cause of cardiomyopathy.²⁰⁸

Medium-chain acyl-CoA deficiency is the most common of the fatty acid oxidation defects and most frequently presents with a Reye disease–like episode, with vomiting, encephalopathy, hypoglycemia, and hyperammonemia. Cardiomyopathy never occurs in medium-chain acyl-CoA deficiency. Cardiomyopathy is a more common presentation of carnitine deficiency and long-chain acyl-CoA dehydrogenase deficiency. Diagnosis is based on the clinical features described earlier: tolerance of 8 to 24 hours of fasting, high plasma free fatty acid levels, normal to low ketone levels, increased urinary organic acids and low plasma carnitine levels. The abnormal findings may not be present between acute exacerbations, and it is crucial to collect specimens during the acute illness. Urine specimens must be collected; blood can be collected on filter paper for tandem mass spectrometry. Treatment consists of supplying adequate glucose, supplementing carnitine, and providing symptomatic support.

Hyperammonemia

Transient hyperammonemia may occur in preterm infants in so-called transient hyperammonemia of the newborn, which is not associated with IEM. Ammonia has significant toxic effects on the brain with associated edema development; however, aggressive therapy may yield completely normal outcomes. Hyperammonemia results in a marked encephalopathy, although patients typically are more hypotonic than in other metabolic encephalopathies; patients may also develop a respiratory alkalosis, which is uncommon in other encephalopathies.

Primary hyperammonemia occurs in the urea cycle defects, but a secondary hyperammonemia may occur in defects of fatty acid oxidation or organic acidemia. Hyperammonemia may also be a consequence of acute hepatic failure (e.g., with acute viral infection, toxin ingestion, and drug reactions, particularly antituberculosis drugs and sodium valproate).

Investigation. Ammonia is very toxic, and therapy must be instituted urgently to remove ammonia.²⁰⁹ It is crucial to collect appropriate diagnostic specimens at the time of presentation because it may be difficult to establish a diagnosis when dialysis and other therapies have been instituted. The following tests enable an approach to diagnosis.

Plasma Ammonia Levels. Hyperammonemia with levels greater than 250 μ mol/L typically are associated with urea cycle defects or transient hyperammonemia of the newborn.

Arterial Blood Gas Analysis. Hyperammonemia with urea cycle defects and transient hyperammonemia of the newborn are not associated with acidosis. Patients often may have a respiratory alkalosis. A metabolic acidosis is more likely to be associated with organic acidopathies.

Tests of the Urea Cycle. Tests of the urea cycle include plasma citrulline, urinary argininosuccinic acid synthetase, and urinary orotic acid.

Amino Acids. Quantitative amino acids may be difficult to interpret but help with diagnosis of conditions such as MMA, isovaleric acidurias, and propionic acidemia.

Carnitine Levels and Acyl Carnitine Analysis. Carnitine and the acyl carnitines may be affected as part of the aminoacidemias.

Management. Principles of management for hyperammonemia consist of the following:

1. Provide intravenous glucose and lipid to decrease ammonia production from endogenous protein breakdown.
2. Administer arginine (L-arginine hydrochloride, 600 mg/kg IV over 1 hour, followed by 2 to 4 mmol/kg/24 h in four divided doses).
3. Administer sodium benzoate (250 mg/kg IV followed by 250 mg/kg/day in four divided doses) and sodium phenylacetate (250 mg/kg IV immediately followed by 250 mg/kg/24 h in four divided doses).
4. Dialyze to remove excessive ammonia. Hemodialysis is the most efficient means to remove ammonia, hemofiltration is the next option (and may be particularly useful in neonates who are too unstable to tolerate hemodialysis), and finally, peritoneal dialysis

may be used. Exchange transfusion has been performed but is relatively inefficient at removal of ammonia.

Metabolic Acidosis

The acid-base environment of the body is very tightly regulated. Overall, the pH is related to the following independent variables: PCO_2 , acids in the body (mostly weak acids such as albumin and phosphates), and the relationships between strong ions (ions that exist almost exclusively in the dissociated ionic form).²¹⁰ While respiratory acidosis is primarily related to the carbonic acid system, specifically with CO_2 retention, metabolic acidosis may be related to a variety of issues including changes in ratio of sodium and chloride (as a consequence of IV infusions of 0.9% saline, or as a consequence of renal tubular dysfunction), or the accumulation of abnormal acids, which may be reflected by an increased anion gap.

A variety of IEM may be associated with proximal renal tubular acidosis (with low anion gap), particularly cystinosis and Lowe syndrome. The most common acids related to an increased anion gap are lactic acid and ketoacids, such as acetoacetate and 3-butyrobutyrate. All of the organic acidopathies and aminoacidopathies may be associated with an increased anion gap. One cause of an increased anion gap acidosis is pyroglutamic aciduria (5-oxoprolinuria) which may be related to glutathione synthetase deficiency²¹¹ or to the combination of malnutrition and exposure to agents such as paracetamol.²¹²

Acid may also be produced by bacterial overgrowth in the bowel and absorbed as occurs in D-lactic acidosis.²¹³ D-Lactic acid is not detected by routine blood tests for lactic acid, which employs a lactic dehydrogenase, but is detected by urinary assays for organic acids. These patients present with acidosis with an increased anion gap.

Patients with organic acidemias rarely present with metabolic acidosis as a primary feature of the illness, and the rest of the clinical presentation frequently provides clues as to the appropriate line of investigation. Investigation of organic acids, however, remains an important component of the investigation of any patient with unexplained metabolic acidosis.

Lactic Acidosis

Lactic acidosis is associated with inadequate oxygenation of tissues, as occurs in hypoxemia or in shock. In this situation, treatment consists of ensuring adequate oxygen content of blood and appropriate cardiac output.

So-called primary lactic acidosis occurs in the absence of hypoxemia and shock. Lactate accumulates either as a consequence of increased production of lactate or because of inadequate clearance and metabolism of lactate (primarily in the liver). Accumulation of lactate may occur without the development of acidosis, depending on the compensatory mechanisms. Many patients with congenital lactic acidosis have increased lactate levels with no acidosis between episodes of exacerbation, although episodes of exacerbation usually are associated with severe lactic acidosis.

Congenital lactic acidoses are variable in presentation, ranging from severe neonatal lactic acidosis with generally poor prognosis to children with milder defects and other children with syndromes such as the MELAS and MERRF syndromes and Leigh disease. In many of these conditions, the lactic acidosis is completely or partially overshadowed by the other clinical features of the conditions. Not all children with defects of mitochondrial energy metabolism have elevated levels.

Lactate production may be caused by increased glycolysis (e.g., glycogen storage disease type I, hereditary fructose intolerance) or by decreased oxidation of pyruvate. Oxidation of pyruvate can be limited by many conditions, including (1) pyruvate dehydrogenase complex deficiency, (2) primary pyruvate carboxylase or holocarboxylase deficiency, and (3) electron transport chain defects (associated with increased lactate pyruvate ratios in blood and CSF). The clinical course of pyruvate dehydrogenase (PDH) deficiency may be extremely variable, and diagnosis is confirmed by studies of enzyme activity in cultured fibroblasts. The lactic acidosis in PDH deficiency can be

ameliorated by a ketogenic diet,²¹⁴ although many factors must be considered before embarking on a ketogenic diet, including the protein content of the diet, particularly if there is associated renal failure, and the long-term problems of ketogenic diets.²¹⁵ Dichloroacetic acid may be helpful in some cases.²¹⁶ Many cases have been reported in which thiamine was associated with clinical improvement,²¹⁷ although high levels may be required.

Lactic acidosis occurs in all of the conditions affecting the metabolism of pyruvate through the tricarboxylic acid cycle. Abnormalities include PDH deficiency and mitochondrial energy cycle defects. The mitochondrial energy cycle problems are frequently associated with persistent lactic acidosis, myopathy, failure to thrive, psychomotor retardation, and seizures. Other symptoms that may be present in mitochondrial energy conditions in children include antenatal problems, cardiomyopathy and cardiac arrhythmias, sensorineural hearing loss, stroke and abnormalities of central respiratory drive, and diabetes mellitus.

Acquired defects in mitochondrial function have been associated with severe lactic acidosis in adults and children on antiretroviral therapy.²¹⁸ Lactic acidosis may also be a secondary phenomenon of defects of organic acid metabolism, including 3-hydroxy-3-methylglutaryl-CoA lyase deficiency, propionic acidemia, and methylmalonic acidemia.

Ketoacidosis

Primary defects in ketone use are rare but include β -ketothiolase deficiency, which may respond rapidly to administration of intravenous glucose. Ketoacidosis is a common feature of many of the organic acidemias, including MSUD, MMA, propionic acidemia, and isovaleric aciduria. Investigation should include measurement of urinary organic acids.

Cardiomyopathy

A wide variety of IEM may present with cardiomyopathy or cardiac arrhythmias. In most of these conditions, other clinical problems and symptoms predominate (such as in glycogen storage disease and organic acidopathies), and the cardiomyopathy is just part of the overall clinical presentation. In these situations, the associations assist in making the diagnosis.

A few conditions may present with cardiac problems apparently in isolation. In the differential diagnosis of myocarditis/cardiomyopathy, many conditions need to be considered, including carnitine deficiency, trifunctional protein defects, or isolated long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency. In the latter two conditions, urinary organic acid analysis *at the time of the acute illness* shows the presence of medium-chain and long-chain dicarboxylic acids. At least one form of very-long-chain acyl-CoA dehydrogenase deficiency can present as an acute cardiomyopathy. For all of these conditions, measurement of acyl carnitines using tandem mass spectrometry allows diagnosis. Diagnosis is confirmed using enzyme activity in cultured fibroblasts. At least one case report²¹⁹ shows that substantial clinical improvement can be achieved by elimination of long-chain fatty acids from the diet (replacing with medium-chain fatty acids). Many disorders of the mitochondrial energy chain have poor myocardial function as one of multiple symptoms, but echocardiography may be needed to show more subtle abnormalities of contractility.

Hepatopathology

IEM can affect the liver in a variety of ways. Patients may present with symptoms ranging from acute hepatic failure to hepatomegaly to chronic hepatitis and cirrhosis. The hepatic dysfunction may present in apparent isolation or in association with cardiac, cerebral, muscle, and renal disease. The presentations of "hepatitis" may be virtually indistinguishable from the presentation of acute viral hepatitis or toxin ingestion. In one study of infants presenting to a transplant service in acute hepatic failure, IEM were responsible for the hepatic failure in 42.5% of the patients. Of these patients, 35% had hepatorenal tyrosinemia, whereas 50% had mitochondrial abnormalities. Hereditary

fructose intolerance and galactosemia together were present in less than 9% of patients.²²⁰

Hepatorenal tyrosinemia may present in the neonatal period as acute hepatic failure. It is difficult to distinguish from acute viral hepatitis because plasma amino acid levels may be similar in both situations. Alpha-fetoprotein levels may be substantially elevated in hepatorenal tyrosinemia and may be a distinguishing feature. The coagulopathy tends to be relatively severe in hepatorenal tyrosinemia, and coagulopathy may be the only presenting feature.²²¹ Patients tend to have moderate to severe anemia. The response to treatment with 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexandion (NTBC) may be dramatic.

Galactosemia is characterized by the development of hypoglycemia in the neonatal period in association with jaundice (initially unconjugated, but subsequently conjugated), marked increase in transaminase levels, some abnormality of coagulation, and moderate hypoalbuminemia. Severe cerebral edema occasionally may be a dominant feature. Management has been reviewed elsewhere.²²² There is a close association with *Escherichia coli* septicemia, and any infant presenting with *E. coli* septicemia should be investigated for galactosemia. Galactosuria clears rapidly if feeds are stopped. A screening test is available on blood collected on filter paper (semiquantitative measure of galactose-1-phosphate uridylyltransferase). The diagnosis can be confirmed by a quantitative measurement of galactose-1-phosphate uridylyltransferase. Wilson's disease may present as acute hepatitis but rarely before age 5 years.

KEY POINTS

1. Although endocrine and metabolic conditions are individually rare, collectively they constitute a significant cause of pathology in the pediatric intensive care unit (PICU).
2. PICU admission is a crucial opportunity to identify endocrine problems and inborn errors of metabolism.
3. Hyper- and hypoglycemia are important metabolic abnormalities and require both an etiologic diagnosis and management. A cause for hypoglycemia or hyperglycemia must always be identified.
4. Inborn errors of metabolism must always be considered as part of the differential diagnosis of critical illness, particularly in infants.
5. Appropriate specimens should be collected at the time of the acute illness, and thereafter the clinician should consult with a specialist laboratory for diagnostic routes.
6. Specialist teams should be consulted early in the course of the illness as few intensivists develop expertise in the management of inborn errors of metabolism.
7. A multidisciplinary team approach is essential for the successful care of affected children.

ANNOTATED REFERENCES

Boles RG, Buck EA, Blitzer MG, et al: Retrospective biochemical screening of fatty acid oxidation disorders in post-mortem livers of 418 cases of sudden death in the first year of life. *J Pediatr* 1998;132:924-933.

The authors devised a biochemical protocol for evaluation of frozen postmortem liver specimens for defects of fatty acid oxidation. On review of specimens from 418 cases of sudden death in the first year of life, they identified 14 cases that closely matched the biochemical profiles seen in fatty acid oxidation defects. No cases of death due to abuse or accidents tested positive. Of deaths that had been classified as infectious, 20% showed multiple abnormalities in the liver specimens, suggesting that fatty acid oxidation defects should be considered as part of the differential diagnosis of sudden or unexpected death, even when an infectious agent has been identified.

Dunger DB, Sperling MA, Acerini CL, et al: ESPE/LWPES consensus statement on diabetic ketoacidosis in children and adolescents. *Arch Dis Child* 2004;89:188-194.

This is an extensive evidence-based review of acute DKA in children and adolescents. Consensus guidelines are presented with references for acute DKA management.

Durand P, Debray D, Mandel R, et al: Acute liver failure in infancy: a 14-year experience of a pediatric liver transplantation center. *J Pediatr* 2001;139:871-876.

This article presents a 14-year review of 80 infants (children <1 year old) admitted to the pediatric hepatology unit or ICU of a French hospital with acute liver failure (defined as prothrombin time >17 seconds and factor V plasma levels <50% of normal). Acute liver failure was a result of inherited metabolic disorders in 42.5% of cases, including mitochondrial respiratory chain disorders, type 1 hereditary tyrosinemia, and urea cycle defects.

Marcin JP, Glaser N, Barnett P, et al: Factors associated with adverse outcomes in children with diabetic ketoacidosis-related cerebral edema. *J Pediatr* 2002;141:793-797.

This is a retrospective study of 61 children (≤18 years old) from 10 U.S. pediatric centers admitted between 1982 and 1997 with DKA and cerebral edema. Only 59% survived without neurologic sequelae, and 28% died or survived in a persistent vegetative state. Intubation with hyperventilation was associated with adverse outcomes after adjustment for confounding variables. Poor outcome also was associated with greater neurologic depression at the time of diagnosis and a higher initial serum urea nitrogen concentration.

Morton DH, Strauss KA, Robinson DL, et al: Diagnosis and treatment of maple syrup disease: a study of 36 patients. *Pediatrics* 2002;109:999-1008.

This article evaluates an approach to the diagnosis and treatment of MSUD. Eighteen neonates were diagnosed as having MSUD between 12 and 24 hours of age using amino acid analysis of plasma or whole blood collected on filter paper. No infant identified before 3 days of age and treated with the protocol became ill during the neonatal period. A further 18 neonates who were intubated at the time of diagnosis responded rapidly to the management protocol without the need for dialysis or hemoperfusion. Follow-up of the 36 infants over more than 219 patient-years showed generally good metabolic control, with good developmental outcome. A management protocol is presented.

Critically ill patients suffer from a variety of physiologic insults that result in a rapidly changing physiologic status, thus making appropriate drug dosing a challenging problem. Understanding how these changes impact pharmacokinetics and pharmacodynamics can result in improved dosing decisions. This chapter reviews the basic principles of pharmacokinetics and pharmacodynamics and how they may be affected by critical illness.

The terms *pharmacokinetics* and *pharmacodynamics* describe the amount of drug in the body at a given time and the pharmacologic effects caused by the drug.¹ Pharmacokinetics describes the movement of a drug into, within, and out of the body over time, whereas pharmacodynamics explains the effects the drug has on the body. Understanding the pharmacokinetic parameters of clearance, volume of distribution, half-life, steady state, and absorption, along with pharmacodynamic principles, such as receptor theory, potency, affinity, tolerance, and minimum effective concentration, can enhance the treatment of critically ill patients.

GENERAL PRINCIPLES OF PHARMACOKINETICS

Clearance, volume of distribution, half-life, and bioavailability are four pharmacokinetic parameters that allow the clinician to better estimate dosing requirements. If the concentration of a drug in a sampled fluid (e.g., plasma, urine, saliva) correlates well with its pharmacologic response (therapeutic or toxic), then the application of pharmacokinetics is likely to be beneficial (Fig. 152-1).

Measurement of the relationship between drug concentration and therapeutic or toxic response in a large number of patients enables the development of a therapeutic range or target concentration for that drug (Fig. 152-2).^{2,3} A multitude of host factors (e.g., hemodynamic status, decreased organ function, nutritional status, concurrent disease states) increase the likelihood that drug dosing based on individualized pharmacokinetic assessment will be beneficial.^{4,5} Gender-related differences can occur in both pharmacokinetic and pharmacodynamic responses.⁶ Individual chapters in this text are devoted to many of these agents and their adjustments for dosage in patients with renal or hepatic failure.

PHARMACOKINETIC MODELS

The pharmacokinetic concepts of clearance, volume of distribution, half-life, and bioavailability are based on enormously complex physiologic principles and use mathematical models that make many assumptions. Most clinically useful pharmacokinetic equations assume one- or two-compartment models (see Fig. 152-2).

When the drug enters the one-compartment model, it is assumed to be instantaneously and completely mixed in a given volume of distribution, resulting in a uniform concentration throughout the compartment. The rate constant K reflects the usual situation of elimination by a first-order, linear process. The drug is assumed to enter the compartment instantaneously in the case of an intravenous bolus dose. If the dosage is administered through oral or intramuscular routes, entry into the compartment is assumed to occur at a rate defined by a

first-order absorption rate constant (K_a), whereas entry into the compartment is assumed to occur at a constant rate described by a zero-order rate constant (R_0) if the drug is administered by intravenous infusion. *Bioavailability* (F) is defined as the fraction of the administered dose that reaches the systemic circulation.

Clearance (CL) is a primary parameter that can be physiologically associated with a particular organ in the body such as the liver or kidney. Clearance is often expressed by the equation $CL = K \times V$, leading to the impression that CL is a function of the parameters K and V . However, this arrangement of the equation is not correct from a physiologic point of view. CL and V are both primary parameters, and K is a secondary parameter. The first-order rate is determined by changes in either CL or V , and the equation is correctly written as $K = CL/V$.

Half-life ($t_{1/2}$) is a useful measure of how quickly a drug is eliminated from the body and is related to the first-order elimination rate constant:

$$t_{1/2} = \frac{\ln(2)}{K} = \frac{0.693}{K} \quad (\text{Equation 1})$$

Specifically, $t_{1/2}$ defines the time taken for the drug concentration to decrease by one-half. In a linear pharmacokinetic system with first-order elimination, $t_{1/2}$ is constant, and it takes the same amount of time for the concentration to fall from 100 to 50 (arbitrary units) as it does to decline from 50 to 25 (Fig. 152-3).

The one-compartment model allows concentrations at any point in time to be calculated:

$$C_2 = C_1 \times \exp^{-K \times \Delta t} \quad (\text{Equation 2})$$

where Δt is the time between measurements C_1 and C_2 . The mono-exponentially decreasing concentration–time curve appears linear when plotted on semi-log coordinates.

Sometimes a drug does not instantly equilibrate with all tissues in the body. This can often be adequately described by a two-compartment model, which is characterized by a rapidly distributing central compartment and a more slowly equilibrating peripheral compartment (Fig. 152-4). The equation describing the concentration–time profile for the two-compartment model is:

$$C = A \times \exp^{-\alpha \times t} + B \times \exp^{-\beta \times t} \quad (\text{Equation 3})$$

The distinguishing feature of this biexponential equation is that when plotted on semi-log coordinates, the concentrations are the sum of two distinct straight lines representing two half-lives. One is the *terminal* or β half-life, and the other is the *rapid distribution* or α half-life. As the rapid distribution exponential becomes negligible in the equation, the slower exponential term dominates, and the concentration–time profile resembles that of a single-compartment drug. Consequently, the equation:

$$C_2 = C_1 \times \exp^{-\beta \times \Delta t} \quad (\text{Equation 4})$$

in which β replaces K , can still be used to predict concentrations, as long as both C_1 and C_2 are in the postdistributive phase. This sum-of-exponentials approach can be extended to three-compartment or even more complex models, but it is difficult to obtain all the concentrations needed to characterize each exponent.

FIGURE 152-1 ■ For concentration monitoring to be useful, there must be a strong relationship between concentration of the drug measured in an easily accessible fluid and concentration at the effect site.

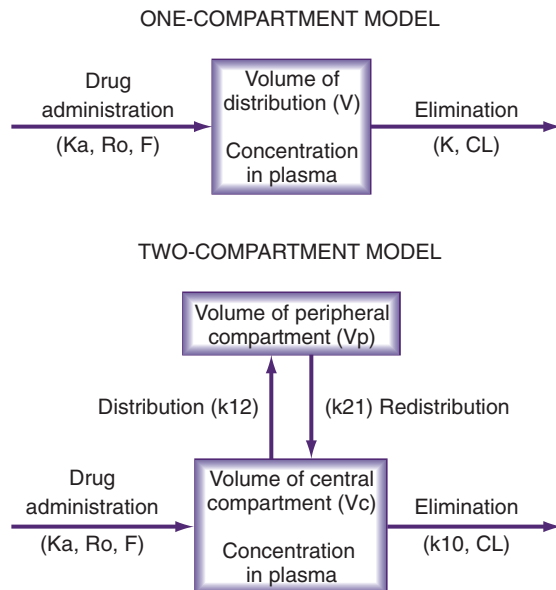

FIGURE 152-2 ■ Pharmacokinetic models simplify complex physiologic process. Concentrations may behave as if the body were a single rapidly equilibrating compartment or follow a more complicated two-compartment model in which a slower distribution phase into tissues is observed. See text for explanation of terms.

Clearance

CL is a primary pharmacokinetic parameter that measures the ability of the body to eliminate a drug. It is often stated that clearance is the volume of blood (plasma) that is completely cleared of drug per unit time. Although this is one way to define clearance, it does not capture the relationship between drug clearance (mL/min) and the rate of drug elimination (mg/h). In pharmacokinetics, the general concept of clearance is also the rate of elimination relative to the concentration. In a first-order pharmacokinetic system, the rate of elimination is proportional to the drug concentration; clearance is this proportionality constant:

$$\text{Rate of elimination} = \text{CL} \times \text{concentration} \quad (\text{Equation 5})$$

Clearance is clinically useful because it can be directly related to the organ of elimination. We can talk about renal clearance, hepatic clearance, or biliary clearance, and the sum of each of the individual

FIGURE 152-3 ■ Log concentration–time curve for a one-compartment model after intravenous administration, illustrating volume of distribution, elimination rate constant, and half-life.

FIGURE 152-4 ■ Log concentration–time curve for a two-compartment model after intravenous administration, illustrating a distribution period (α) and postdistribution period (β). Concentrations C1 and C2 reflect both distribution and elimination processes, whereas concentrations C3 and C4 reflect postdistribution elimination processes.

clearances is the total body clearance. This allows us to adjust doses in response to changes in organ function. A patient with developing renal failure is likely to require a reduction of the dose of a drug that is eliminated by the kidney but not necessarily a dose reduction of a drug that is eliminated by the liver. For example, if the clearance of a drug is known to be 50% renal and 50% hepatic and renal function is decreased by 50%, it is necessary to reduce the dose by only 25% to maintain the same concentration.

The area-under-the-curve (AUC) is a useful measure of drug exposure and results from dose and CL:

$$\text{AUC} = \frac{\text{Dose}}{\text{CL}} \quad (\text{Equation 6})$$

This concept is similar to a steady-state concentration (C_{ss}) being considered as the measure of drug exposure during a continuous intravenous infusion. The C_{ss} is solely a function of the infusion rate (R_o) and CL:

$$C_{ss} = \frac{R_o}{\text{CL}} \quad (\text{Equation 7})$$

Notice that C_{ss} is not a function of the volume of distribution. Though counterintuitive, doubling the volume of distribution will not result in a halving of C_{ss} . The important point is that the equation is predicting the concentration at a steady state. During a constant infusion, rapidly doubling the volume of distribution will only transiently halve the concentration. If clearance remains unchanged, the concentration will return to the same C_{ss} .

With intermittent dosing, drug concentrations go up and come down during each dosing interval. The average C_{ss} ($C_{ss,avg}$) is a time-averaged concentration (i.e., the mean of all concentrations during the dosing interval); it is also a function of clearance and the dosing rate. In the case of oral administration, the dosing rate is a function of the dose administered (D), dosing interval (τ), and F :

$$C_{ss, avg} = \frac{F \times D / \tau}{CL} \quad (\text{Equation 8})$$

As before, the overall drug exposure is not influenced by the volume of distribution, but it does change in proportion to changes in clearance or the dosing rate through changes in F , D , or τ .

Volume of Distribution

The volume of distribution (V) is another primary pharmacokinetic parameter and is useful for determining the change in drug concentration for a given dose. After an intravenous bolus dose in a one-compartment pharmacokinetic model, the change in concentration (ΔC) between the maximum concentration (C_{max}) and the concentration immediately before the dose is administered is a function of the dose (D) and the V :

$$\Delta C = \frac{D}{V} \quad (\text{Equation 9})$$

This equation is useful for predicting both the concentration after a first bolus dose and the increase in concentration at any point in time after a bolus dose. If a concentration before a bolus dose is known, the equation can be used to predict the increase in concentration after the dose is administered (see Fig. 152-3). This equation is also useful for estimating the dose needed to reach a given concentration. If it is known that the volume of distribution is 0.45 L/kg and a C_{max} of 10 mg/L is desired after the loading dose, the dose is estimated to be $10 \text{ mg/L} \times 0.45 \text{ L/kg} = 4.5 \text{ mg/kg}$. This equation only predicts loading doses and not maintenance doses. A steady-state condition is not necessary, which is common in critical care.

The value for the volume of distribution does not necessarily coincide with any particular physiologic space. The veracity of this statement becomes readily apparent when one considers a drug such as digoxin which has a volume of distribution of approximately 440 L. Clearly, a volume of distribution of that magnitude cannot have a relationship to any physiologic space in an average-sized human. Therefore, the term *apparent volume of distribution* is often used.

The concept of the volume of distribution gets more complex when more than one compartment is needed to describe the pharmacokinetics of a drug. Mathematically, the volume of distribution is a hypothetical volume that is needed to relate the amount of drug in the body to a measured concentration in a fluid (plasma). Unlike the one-compartment model, wherein the entire drug in the body is regarded as being in a single compartment until it is eliminated, drug also circulates through additional compartments in a multicompartment model. In this situation, the volume of distribution must increase as drug distributes to other compartments until distribution equilibrium among all compartments is reached. Technically, an infinite number of volumes of distribution are observed as this equilibration process occurs, but only three are commonly defined. The *volume of distribution of the central compartment* (V_c) is the volume of the usual sampling compartment; it is always the smallest volume term. Immediately after the administration of an intravenous bolus, all added drug is in the

central compartment, and V_c can be used to calculate a change in concentration.

The volume of distribution increases over time until a *distribution equilibrium* is reached among all compartments. This is the largest value for the volume of distribution. The fact that the distribution equilibrium has occurred can be discerned from a log concentration versus time plot (see Fig. 152-4). The curve becomes log linear when the rate of drug entry into each peripheral compartment equals the rate of return from each compartment. Because it is often calculated using the clearance and β or terminal elimination half-life, this volume is often called V_β :

$$V_\beta = \frac{CL}{\beta} \quad (\text{Equation 10})$$

The *steady-state volume of distribution* (V_{ss}) is the sum of the volumes of all the compartments in the model. If a drug were infused to steady state, V_{ss} would be the proportionality constant relating C_{ss} to the total amount of drug in the body.

Half-Life

Half-life ($t_{1/2}$) is defined as the time taken to reduce the drug concentration by half (see Fig. 152-3). Half-life is referred to as a *secondary parameter* because it is a function of two primary parameters, clearance and volume of distribution:

$$t_{1/2} = \frac{\ln(2) \times V}{CL} = \frac{0.693 \times V}{CL} \quad (\text{Equation 11})$$

A change in either clearance or volume of distribution results in a proportional change in half-life.

Because the half-life characterizes how rapidly concentrations decrease over time, it is used to determine how frequently a drug needs to be dosed. Drugs with rapid half-lives need to be dosed more frequently than drugs with longer half-lives. The half-life for an aminoglycoside is relatively short in patients with good renal function, and the drug may require dosing every 6 hours. In patients with poor renal function, the half-life is longer, and dosing may be prolonged to 24-hour intervals to maintain appropriate peak and trough concentrations. In the critical care patient, the development of renal failure can significantly change aminoglycoside clearance, and the accompanying change in drug half-life will necessitate a change in dosing interval.

In a one-compartment system with constant clearance and volume of distribution, drug half-life is also constant. However, in a multicompartment model, the volume of distribution increases over time as drug equilibrates into tissue compartments until V_β is reached. According to the previous equation, the half-life also increases over time and eventually reaches a maximum at $t_{1/2}\beta$ (see Fig. 152-4).

In multicompartment models, there is usually one half-life of interest for each compartment. These half-lives are derived from the hybrid time constants associated with each compartment. In a two-compartment model, these two exponentials are typically called α and β and are arbitrarily termed the *rapid* and *slow exponents*, respectively. These time constants give rise to the distribution $t_{1/2}\alpha$ and the slower or terminal $t_{1/2}\beta$. One useful way to think about distribution half-lives is analogous to the standard way of thinking about any half-life. In the one-compartment model, it takes five half-lives for 97% of the drug to be eliminated from the body. The situation is similar for each exponent, but the interpretation is that it takes five distribution half-lives for that exponent to become negligible in the sum of exponentials equation—that is, for the rapid distribution phase to reach equilibrium.

Most drugs have a rapid distribution phase that could be detected if concentrations were measured frequently enough. Aminoglycosides are an illustrative example of this concept because they have a rapid, although not instantaneous, distribution phase (Fig. 152-5). With a distribution phase half-life of 5 to 10 minutes, it would take

FIGURE 152-5 ■ If an aminoglycoside (tobramycin) is administered by intravenous infusion over 30 minutes, the peak concentration will be higher than with infusion over 60 minutes, but the total area under the curve will be the same. In therapeutic drug monitoring, if sample C1 is obtained during the distribution phase and paired with C3, the calculated half-life will be shorter than if two postdistribution concentrations (C2 and C3) are paired together.

approximately 25 to 50 minutes before the log-linear elimination phase could be observed. This results in the recommendation to wait approximately 1 hour after the end of an infusion before sampling blood to measure an aminoglycoside concentration. If a blood sample is obtained before this time, the drug will still be in the distribution phase, and the concentration measured will lead to underestimation of the drug half-life. In addition, slowly equilibrating compartments have been demonstrated when aminoglycoside concentrations are measured during washout.⁷ Aminoglycosides are usually dosed frequently enough so that the slowly equilibrating compartment is not detected.

Bioavailability

The extent of drug absorption, termed *bioavailability* (F), is generally referenced to the exposure when the drug is intravenously administered. This parameter is determined by comparing the AUC of the drug intravenously administered to that of the same drug administered via another route. The bioavailability of a drug intravenously administered is regarded as being 100% (i.e., F = 1.0), and other routes of administration (e.g., oral dosing, intramuscular injection) often have a reduced bioavailability (e.g., F = 0.8, or 80% bioavailability). Bioavailability is a function of the extent of absorption and the amount of drug metabolized before entering the systemic circulation (first-pass effect). Drugs with low bioavailability either cannot be administered by any route other than the intravenous one (e.g., sodium nitroprusside, dobutamine) or require higher doses when administered via the oral route compared with the intravenous route (e.g., furosemide, morphine, propranolol). Alternative routes of administration (e.g., rectal, topical, subcutaneous injection, intramuscular injection) are occasionally used in critically ill patients, owing to poor oral bioavailability. These routes all suffer from problems with delayed or poorly predictable serum concentrations. Vasoconstriction, hypoperfusion, edema, gastric suctioning, ileus, diarrhea, and enhanced gastrointestinal motility are all common problems in critically ill patients that can adversely affect bioavailability.

The *first-pass effect* limits drug absorption in three ways. As some drugs enter the gut wall, they are susceptible to transport proteins (primarily P-glycoprotein) that actively pump the molecules back into the lumen of the gastrointestinal tract.⁸ Molecules that escape this

FIGURE 152-6 ■ With intermittent dosing, concentration profiles also approach steady state wherein peak and trough concentrations during one cycle are reproducible in the next cycle.

process are then subjected to metabolism by enzymes in the gut wall. Those that escape gut metabolism enter the hepatic circulation and are subjected to metabolism in the liver before their first opportunity to be presented to the systemic circulation.⁹ Drugs that have a high hepatic extraction ratio (i.e., are very efficiently removed by the liver) are most likely to show decreased bioavailability due to this first-pass effect; conversely, the bioavailability of these drugs increases if liver dysfunction decreases the hepatic extraction ratio.

Steady State

After an infusion is started, drug concentrations increase and eventually reach a concentration that does not change over time. At this point, the amount of drug entering the body is equal to the amount leaving it, and steady-state conditions apply. During intermittent dosing, drug concentrations accumulate over time, and eventually a steady state is attained when the concentration profile over each interval resembles all other steady-state profiles (Fig. 152-6). In the clinical setting, the measurement of drug concentration is often delayed for a period equal to five half-lives because at that point the concentration will reflect 97% of the final C_{ss}.

PHARMACODYNAMICS

Pharmacodynamics is the study of the relationship between the concentration of a drug and its pharmacologic effect. Complex pharmacodynamic models with many linked submodels are routinely employed during drug development to determine drug-dosing regimens. In clinical practice the relatively simple E_{max} model is often adequate¹⁰:

$$\text{Effect} = \frac{E_{\text{max}} \times \text{concentration}}{EC_{50} + \text{concentration}} \quad (\text{Equation 12})$$

Graphically, this equation has a hyperbolic shape (Fig. 152-7) with parameters E_{max} and EC₅₀. E_{max} represents the maximal effect attainable due to the drug. The EC₅₀ is the concentration at which half the maximal effect is observed; it is thus a measure of drug potency. The model dictates that increasing doses of the drug do not proportionately increase its effect; eventually, the effect of the drug begins to reach a plateau. If the drug concentration is expected to be less than EC₅₀, increasing the dose will produce a nearly proportional increase in effect. However, as concentrations exceed the EC₅₀, an increase in dose may not be warranted. The increased concentrations will produce

FIGURE 152-7 ■ The Emax pharmacodynamic model illustrates that as drug concentrations continue to increase, the increases in drug effect become progressively smaller. Drug A has a lower EC₅₀ (3) than drug B (15) and is said to be more potent than drug B.

FIGURE 152-8 ■ Pharmacodynamic effects often lag behind the matching pharmacokinetic model. In this instance, maximum concentration in blood occurs at 1 hour, whereas maximal drug effect occurs between 2 and 3 hours.

a lesser increase in desired effect and may place the patient at risk for development of adverse drug-related effects.

Time does not appear in the Emax model, and concentrations are explicitly defined as C_{ss} so that the effect resulting from a given concentration is considered to be a steady-state effect. This model applies when drug in the plasma rapidly equilibrates with drug at the site of action, and there is no indirect mechanism between the concentration at the site of effect and the effect itself. The more common situation is that the effect lags somewhat behind the concentration (Fig. 152-8). If concentrations are going up and coming down over time, as would be expected with an intermittent intravenous or oral dosing schedule, the effect is also expected to go up and down over time, but the time frames may not coincide exactly. For example, the plasma concentration might peak at 1 hour and the effect might peak several hours later. There is a mismatch or disequilibrium between concentration and effect, and a plot of effect versus concentration, with the points connected in time order, yields a hysteresis loop. For any given concentration, there are two effects, one on the upswing of the concentration–time curve and another on the downswing.

The pharmacodynamic effects noted with a given drug result from the drug's interaction with receptors and the resultant activation or inhibition of effects mediated by that receptor. These effects may be either the desired therapeutic action or an unwanted toxic effect. Generally, it is assumed that the intensity of effect produced by the drug is a function of the quantity of drug at the receptor site, whereas relative potency results from varying degrees of selectivity for the receptor and the receptor's affinity for binding the drug. More potent drugs elicit a given effect at lower concentrations than less potent drugs.

Drugs that stimulate a response from the receptor are *agonists*, and those that inhibit a response from the receptor are *antagonists*. Because antagonists have no effect of their own at the receptor, the net effect depends on both the concentration of the antagonist and the agonist being blocked. The relative concentration of the agonist compared with the antagonist primarily determines the effect observed when an antagonist is competing for the same binding site as the molecule or drug that stimulates the receptor. Irreversible antagonists, however, either bind with very strong affinity to the receptor so they cannot be displaced or bind to another site on the substrate that interferes with binding at the receptor. The effect of irreversible antagonists is independent of the agonist's concentration and results in a decrease in the maximal effect of the agonist. The duration of effect for irreversible antagonists is determined by the rate of turnover for the receptor.

Tolerance to a drug is seen when the response at a given dose decreases. This may be a result of receptor downregulation (decreased number or sensitivity of receptors) or enzyme induction (increased metabolism). Cross-tolerance, as is commonly seen with opioids, occurs when similar drugs act on the same receptor.

PROTEIN BINDING

Many drugs are bound to plasma proteins, and the terms *bound drug concentration* (C_b), *unbound (or free) drug concentration* (C_u), *total (bound plus unbound) drug concentration* (C_{tot}), and *unbound (or free) fraction* (f_u) are frequently used:

$$\begin{aligned} C_{tot} &= C_u + C_b \\ f_u &= \frac{C_u}{C_{tot}} \end{aligned} \quad (\text{Equation 13})$$

The pharmacokinetic concepts concerning the implications of protein binding were reviewed in 2002 by Benet and Hoener.¹¹ They demonstrated that changes in plasma protein binding have little clinical relevance as they rarely result in changes to the steady-state unbound concentration. To better understand this concept, the relationships among unbound drug exposure, total drug exposure, and pharmacodynamic effect must be considered. One of the more useful measures of exposure is the AUC, and the unbound AUC (AUC_u) determines drug effect:

$$AUC_u = f_u \times AUC = f_u \times F \times \frac{\text{Dose}}{CL} \quad (\text{Equation 14})$$

where f_u is the fraction unbound, F is the bioavailability, and CL is the clearance.

After standard, well-stirred model assumptions are made regarding high- and low-clearance drugs, something interesting occurs when the equations for clearance and bioavailability are substituted into the equation for AUC_u. For all drugs administered orally and eliminated hepatically, the f_u term cancels out of the equation. Unbound drug exposure is not a function of f_u at steady state, and there should be no changes in pharmacologic effect with changes in protein binding. Similarly, it can be shown that AUC_u for all drugs with low extraction ratios—whether administered orally or by the intravenous route, and whether eliminated by the liver or nonhepatically—is not a function of f_u. Again, changes in protein binding will not result in changes in

the steady-state exposure to the unbound drug. It is important to emphasize that AUC_u refers to the AUC based on unbound concentrations. The AUC based on total concentrations, AUC_{tot} , can be calculated from this equation: $AUC_{tot} = AUC_u/f_u$. If the protein binding of a drug changes and f_u is doubled, AUC_{tot} will be halved, and AUC_u will remain the same. The expression for AUC_u retains the f_u term for all high-clearance drugs administered intravenously (regardless of clearance route) and for high-clearance drugs administered orally that are eliminated by extrahepatic pathways.

To address this issue, Benet and Hoener reviewed pharmacokinetic data on 456 drugs from the literature. No orally administered drug with a high extraction ratio and nonhepatic clearance met the criterion for significant (>70%) protein binding. Only 25 (5%) of the 456 drugs had high extraction ratios, were not administered by the oral route, and met the criterion for which protein binding may influence drug exposure. However, many of these 25 agents are routinely used in critical care (Table 152-1).

In critically ill patients, protein concentrations can change quickly. This is particularly true of the acute-phase reactant, α_1 -acid glycoprotein (AAG). In addition, some patients (e.g., those undergoing dialysis or those with cachexia) have altered protein binding.¹² The extent of protein binding, route of administration, route of elimination, and extraction ratio of the drug all should be considered when

determining whether a change in binding is likely to result in a change in effect.

As a final note on protein binding, care must be taken when evaluating total drug concentrations in patients with altered protein binding. Consider the case of phenytoin. The percentage of unbound drug is typically 10% but is approximately doubled in patients receiving hemodialysis (Table 152-2). If phenytoin were administered as a standard dose to all patients, there would be no problem; phenytoin is a low-clearance drug, and protein binding should not influence overall unbound exposure whether the drug is administered orally or intravenously. However, phenytoin concentrations are often obtained for the purposes of therapeutic drug monitoring, and efforts are made to achieve circulating levels within the commonly accepted therapeutic range of 10 to 20 mg/L. In patients with normal protein binding, this exposure equates to an unbound therapeutic range of 1 to 2 mg/L. In patients with 20% unbound drug, the desired unbound range is still 1 to 2 mg/L, but the range based on total concentration is approximately halved. In cases of higher f_u , if phenytoin dosing is increased to achieve 10 to 20 mg/L, toxicities may be observed because the unbound concentration will be twice the desired value.

■ NONLINEAR PHARMACOKINETICS

The application of pharmacokinetics to therapeutic drug monitoring becomes considerably more difficult with drugs that exhibit nonlinearities. With linear pharmacokinetics, parameters are stable over time and across concentrations. Doubling of the dose results in doubling of the concentration, and a given dose provides the same AUC regardless of the dosing history. *Nonlinear pharmacokinetics* is a term used when the principle of superposition no longer holds. An increase in dose may result in an increase in concentration that is more than or less than proportional, or it may result in clearance changes over time. There are several common types of nonlinearities that occur in the clinical setting.

Phenytoin is the classic example for nonlinear elimination. Increases in a phenytoin dose can result in greater than proportional increases in concentration. In any pharmacokinetic system, clearance is defined as the rate of elimination relative to the concentration. Hence, an instantaneous rate of elimination can be defined as follows:

$$\text{Rate of elimination} = CL \times C \quad (\text{Equation 15})$$

In a linear elimination process, clearance is constant, and doubling the concentration doubles the rate of elimination. In the case of phenytoin with nonlinear elimination, clearance is not constant. Nonlinear elimination occurs because the metabolic pathway responsible for the elimination of the drug is saturable. The enzyme system has a maximum rate of metabolism that can be approached at therapeutic concentrations of phenytoin. These principles can be better understood by considering the rate of elimination described by the Michaelis-Menten equation (Fig. 152-9). It has two parameters, the *maximum rate of elimination* (V_{max}) and the *concentration that results in one-half the maximum rate* (K_m):

TABLE 152-1

25 Drugs for Which Changes in Protein Binding May Influence Clinical Drug Exposure After Intravenous or Intramuscular Administration*

| | |
|------------------------|--------------------|
| Alfentanil | Itraconazole |
| Amitriptyline | Lidocaine |
| Buprenorphine | Methylprednisolone |
| Chlorpromazine | Midazolam |
| Cocaine | Milrinone |
| Diltiazem | Nicardipine |
| Diphenhydramine | Pentamidine |
| Doxorubicin | Propofol |
| Erythromycin | Propranolol |
| Fentanyl | Remifentanyl |
| Gold sodium thiomalate | Sufentanil |
| Haloperidol | Verapamil |
| Idarubicin | |

*Criteria for selection included >70% protein binding and hepatic clearance >6.0 mL/min/kg or nonhepatic extraction ratio clearance $\geq 0.28 \times$ renal blood flow (>4.8 mL/min/kg). Modified from Benet LZ, Hoener BA. Changes in plasma protein binding have little clinical relevance. Clin Pharmacol Ther 2002;71:115–121.

TABLE 152-2

Effect of Decreased Protein Binding on Bound and Unbound Concentrations of Phenytoin

| CONCENTRATION | CONCENTRATIONS OF PHENYTOIN AT THERAPEUTIC RANGE (mg/L) | | RESULT OF ERRONEOUS INCREASE IN PHENYTOIN DOSE IN PATIENT WITH DECREASED PROTEIN BINDING* |
|---------------------|---|---|---|
| | TYPICAL PATIENT | PATIENT WITH PROTEIN BINDING DECREASED BY 50% | |
| Total (C_{tot}) | 20 | 10 | 20 |
| Unbound (C_u) | 2 (10%) | 2 (20%) | 4 (20%) |
| Bound (C_b) | 18 | 8 | 16 |

*Because of the altered protein binding, C_{tot} is less when C_u is in the therapeutic range (i.e., 2 mg/L). During therapeutic drug monitoring, it is the C_{tot} that is measured. If the decreased protein binding is not taken into account and the phenytoin dose is increased to achieve a C_{tot} of 20 mg/L, the actual C_u will double and toxic effects could ensue.

FIGURE 152-9 ■ The Michaelis-Menten model demonstrates elimination as a nonlinear function of concentration, with characteristics including a maximum rate of elimination (V_{\max}) and a concentration at which one-half of the maximum rate of elimination occurs (K_m).

$$\text{Rate of elimination} = \frac{V_{\max} \times C}{K_m + C} \quad (\text{Equation 16})$$

Although the parameters V_{\max} and K_m are constant, it can be seen that clearance is a function of concentration (C). The clearance of a drug decreases as the concentration increases:

$$CL = \frac{\text{Rate of elimination}}{C} = \frac{V_{\max}}{K_m + C} \quad (\text{Equation 17})$$

Although enzyme systems do have maximal rates, the usual drug concentrations attained in the clinical setting are considerably lower than K_m , the quantity $V_{\max}/(K_m + C)$ is minimally influenced by concentration, and clearance becomes constant. Therefore, even

though many drugs are metabolized by hepatic enzymes, few drugs of clinical interest display detectable nonlinear elimination.

At steady state, the amount of drug eliminated every day must equal the dose taken, and the elimination rate equals the dosing rate. After rearranging the equation for the C_{ss} :

$$C_{ss} = \frac{\text{Dosing rate} \times K_m}{V_{\max} - \text{Dosing rate}} \quad (\text{Equation 18})$$

This equation shows that an increase in dosing rate produces a greater than proportional increase in the C_{ss} . Furthermore, if the dosing rate exceeds V_{\max} , a C_{ss} will never be attained.

Another type of nonlinearity is time-dependent pharmacokinetics as demonstrated by carbamazepine inducing its own metabolism.¹³ This autoinduction causes the clearance of carbamazepine to increase over time. It is important to gradually increase the dose of carbamazepine during the first few weeks of therapy up to the expected maintenance dose to avoid toxicities related to elevated concentrations.

Protein binding also can become saturable with some drugs. Intuitively, one might think that saturation of protein binding would result in higher unbound drug concentrations available to exert desirable effects and toxicities, but it must be kept in mind that the organs responsible for drug clearance are eliminating unbound drug. Therefore, unless the clearance of a drug also changes, the steady-state unbound concentration will remain constant in the face of saturable protein binding. The total concentration is a function of the unbound concentration and the fraction unbound:

$$C_{\text{tot}} = \frac{C_u}{f_u} \quad (\text{Equation 19})$$

If the fraction unbound increases at higher unbound concentrations, total concentrations do not increase in proportion to unbound concentrations. This can be perplexing in therapeutic drug monitoring situations. Increases in dose produce less than expected increases in total concentration. As the dose is pushed higher to reach desired total concentrations, toxicities may be observed because saturable binding causes the unbound concentration to be greater than expected.

KEY POINTS

1. Pharmacokinetic analysis is likely to be useful when there is a strong relationship between drug concentration and the pharmacologic response associated with a given drug concentration.
2. Although many of the complex underlying principles of drug distribution and elimination are simplified by the one-compartment model, it is widely employed for patient care because it successfully predicts future drug concentrations with sufficient accuracy to be clinically useful.
3. Volume of distribution (V) reflects the resulting concentration from a given drug dose and is not directly associated with a physiologic space.
4. Drug half-life ($t_{1/2}$) is a measure of how quickly a drug is eliminated from the body; it is related to the first-order elimination rate constant (K) by the equation: $t_{1/2} = 0.693/K$.
5. Clearance (CL) is a primary pharmacokinetic parameter that describes the efficiency of the body in eliminating a drug and is given by the volume of blood completely cleared of drug per unit time.
6. The area-under-the-concentration–time curve (AUC) is a measure of drug exposure; it is determined by the dose of drug and the clearance through the relationship: $AUC = \text{Dose}/CL$.
7. In a one-compartment pharmacokinetic model, the change in drug concentration (ΔC) can be predicted by the dose of drug and volume of distribution through the relationship: $\Delta C = \text{Dose}/V$.
8. Half-life ($t_{1/2}$) measures the amount of time needed for a drug concentration to decrease by 50%; it changes in proportion to changes in either V or CL , as reflected by the equation $t_{1/2} = 0.693 \times V/CL$.
9. Most drugs demonstrate at least two compartments when pharmacokinetics is examined closely; changes in concentration reflect a short distribution phase (α) and a longer elimination phase (β).
10. After five half-lives of either α (the distribution $t_{1/2}$) or β (the elimination $t_{1/2}$), a drug will be 97% distributed throughout the body or eliminated from the body.
11. The extent of drug absorption is termed *bioavailability* (F); it is generally referenced to concentrations when the drug is intravenously administered.
12. The *first-pass effect* refers to the elimination of drug that is absorbed orally but then metabolized and/or secreted by enzymes in either the liver or the gut wall before reaching the systemic circulation.

KEY POINTS—cont'd

13. Pharmacodynamics is the study of the relationship between the concentration of drug and its pharmacologic effect.
14. The Emax pharmacodynamic model defines a hyperbolic relationship between effect and dose that allows less than proportional increases in response as concentrations increase.
15. Observed pharmacologic effects often lag behind the serum concentration eliciting the effect and can be observed as a hysteresis loop when effect-concentration pairs are connected in time order.
16. Antagonists may inhibit an effect at a receptor through concentration-dependent competitive blocking or by binding irreversibly to the receptor.
17. Although many drugs are bound to some extent by plasma proteins, their effect is determined by the unbound concentration; changes in protein binding do not have a clinically significant effect in most clinical patients.
18. Nonlinear elimination is exhibited when CL changes with changes in drug concentration, as reflected by the Michaelis-Menten equation, $CL = V_{max}/(K_m + C)$, wherein V_{max} is the maximum rate of elimination, K_m is the concentration of drug that results in one-half the maximum rate, and C is the concentration of drug.

Poisoning: Overview of Approaches for Evaluation and Treatment

Brenna Farmer and Donna L. Seger

Patients presenting to the hospital with overdoses and poisonings should undergo an initial evaluation to determine if a specific poisoning can be determined that would lead to specific management options. History and physical examination are key to determine what poisoning, such as a toxidrome, a syndrome related to a toxic exposure (cholinergic, anticholinergic, sympathomimetic, opioid, sedative-hypnotic, or withdrawal syndromes), could be causing a patient's presentation. Once a poisoning or overdose has been identified, management can be determined. Management options can include gastrointestinal decontamination, enhancing elimination, and/or use of antidotes. Additionally, some poisonings and overdoses only require supportive care.

HISTORY

A thorough poison history should be obtained. Necessary elements include suspected ingestion, amount ingested, time of ingestion, and any possible coingestants. Other important elements include past medical history, medication history, social history, and family history. Access to other medications in the home, including dietary and herbal supplements and over-the-counter medications, must be determined. Review of symptoms, including if vomiting was present, will also be important when determining if gastrointestinal decontamination would be useful.

PHYSICAL EXAMINATION

Poisoned patients should undergo a thorough physical examination to determine if a toxidrome is present. Specific elements of the examination that allow for this determination include mental status; pupil size and reactivity; mucous membrane evaluation; cardiac and pulmonary examinations; abdominal examination for bowel sounds and presence of palpable bladder; skin examination for temperature, flushing, and perspiration; muscle tone; and neurologic examination for presences of tremors, clonus, and reflexes. See [Table 153-1](#) for toxidrome physical exam findings.

LABORATORY ANALYSIS

While determining if a poisoning has occurred or trying to determine the cause of an undifferentiated poisoning, some laboratory values can be helpful. Common laboratories to obtain include basic metabolic panel for electrolytes and to determine anion gap; ethanol, acetaminophen (paracetamol), and salicylate concentrations; liver function tests for transaminases; serum osmolality if toxic alcohol is suspected; blood gas for pH. These laboratories can aid in narrowing the differential diagnosis when a patient has overdosed or make the diagnosis in acetaminophen or salicylate poisoning.

TOXICOLOGY LABORATORY

Urine drug screens are usually obtained in poisoned patients; however, there is no standardized screen. Interpretation of urine drug screen results depends on the clinician's knowledge of which toxins have been screened and whether confirmatory testing (ideally performed by a different analytic method) will follow. The length of time required to

receive results varies among hospitals. Quantitative serum drug testing is done when quantitation of a toxin is clinically relevant, as is the case for acetaminophen, anticonvulsant agents, salicylates, digoxin, ethanol, ethylene glycol, methanol, iron, lithium, and theophylline. The clinician caring for the poisoned patient should discuss drug testing with the analytic toxicologist so that the results of testing can be appropriately interpreted. The clinical value of analytic toxicology testing depends on the clinician's ability to understand and interpret the results.

Once a poisoning has been identified, specific management options may be necessary, from gastrointestinal decontamination and enhancing elimination, to use of specific antidotes.

GASTROINTESTINAL DECONTAMINATION

The theory of gastric decontamination is that removal of toxins is done first from the stomach (where absorption is poor) before they move into the small intestine (where absorption is more rapid) so as to decrease the toxicity of the poisoning. Because of controversies regarding the role of gastrointestinal decontamination (GID), senior toxicologists from the American Academy of Clinical Toxicology and the European Association of Poison Centres and Clinical Toxicologists (EAPCCT) agreed to collaborate on the production of Position Statements on GID treatments. These statements, published in 1997, are systematically developed guidelines founded on a criteria-based critical review of all relevant scientific literature.¹ All Position Statements were updated in 2004, with some getting new updates in 2014 ([Table 153-2](#)). GID included ipecac, gastric lavage, single-dose activated charcoal, cathartics, and whole-bowel irrigation.

Ipecac

Ipecac, prepared form of the *Cephaelis acuminata* or *Cephaelis ipecacuanha* plants, is no longer recommended for routine use in the management of poisoned patients as there is no evidence that it improves outcomes.² Vomiting within 30 minutes after administration is caused by local irritation of the gastric mucosa, and after 30 minutes vomiting is centrally induced.³ In experimental studies, the amount of marker removed by ipecac treatment was highly variable and diminished with time.²

Gastric Lavage

Gastric lavage should not be employed routinely in the management of poisoned patients as there is little clinical evidence of benefit and no controlled trials showing benefit.⁴ If performed due to a potentially life-threatening poison ingestion, an experienced provider should perform the lavage due to the complications that can occur.⁴ Gastric lavage involves a large-bore (36F-40F) orogastric tube passed into the stomach, after which small volumes (200-300 mL) of liquid are alternately administered and aspirated. Comatose patients and those with loss of their protective airway reflexes should have an endotracheal tube placed prior to this procedure. An oral airway prevents biting of the tube. The amount of stomach contents removed via this procedure is highly variable and decreases with time.⁵⁻⁷ The procedure can actually push stomach contents into the intestine.⁸ Contraindications

TABLE 153-2**Position Statement Summaries on
Gastrointestinal Decontamination
Treatments**

| MANAGEMENT | RECOMMENDATION |
|----------------------------------|---|
| GASTRIC DECONTAMINATION | |
| Ipecac | Syrup of ipecac should not be administered routinely for the management of poisoned patients. ² |
| Gastric lavage | Gastric lavage should not be employed routinely in the management of poisoned patients. ⁴ |
| Single-dose activated charcoal | Single-dose activated charcoal should not be administered routinely in the management of poisoned patients. ¹¹ |
| Cathartic | Administration of a cathartic alone has no role in the management of poisoned patients. Routine use of a cathartic in combination with activated charcoal is not endorsed. ¹⁸ |
| Whole-bowel irrigation | Whole-bowel irrigation should not be used routinely in the poisoned patient. ¹⁹ |
| ENHANCE ELIMINATION | |
| Multiple-dose activated charcoal | Multiple-dose activated charcoal should be considered if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline. ²⁰ |
| Urinary alkalinization | Urinary alkalinization should be considered as first-line treatment in patients with moderately severe salicylate poisoning who do not meet the criteria for hemodialysis. Urinary alkalinization also should be considered for patients with severe poisoning due to 2,4-dichlorophenoxyacetic acid or mecoprop (MCP) poisoning. Urinary alkalinization is not recommended as first-line treatment for cases of phenobarbital poisoning, because multiple-dose activated charcoal is superior. ²¹ |

include loss of protective airway reflexes (unless the patient is endotracheally intubated), ingestion of a corrosive substance or a hydrocarbon, gastrointestinal pathology, and other medical conditions that could be worsened by the use of lavage. Complications of the procedure include aspiration, laryngospasm, hypoxia, hypercapnia, mechanical injury, and fluid and electrolyte imbalances in children.⁹

Single-Dose Activated Charcoal

Activated charcoal is made when coconut shells, peat, wood, or other materials undergo controlled pyrolysis and are subsequently activated by heating in steam or air at high temperatures. Activation creates multiple internal pores and the small particle size necessary for adsorption. The particles have a large surface area and are capable of adsorbing poisons with varying affinities. Although in vitro studies demonstrate adsorption of many drugs to activated charcoal, animal studies reveal variable reductions in the systemic uptake of marker substances.^{9,10} Volunteer and clinical studies have not demonstrated that single-dose administration of activated charcoal improves outcome. Therefore, single-dose activated charcoal should not be administered routinely in the management of poisoned patients. Administration of activated charcoal may be considered if a patient has ingested a potentially toxic amount of poison (that is known to be adsorbed to charcoal) not longer than 1 hour before treatment as its effectiveness decreases over time. There is no evidence that the administration of activated charcoal improves outcome.^{11,12}

Contraindications to the administration of activated charcoal include decreased level of consciousness and unprotected airway, ingestion of caustic substances or hydrocarbons, gastrointestinal pathology, and medical conditions that could be further compromised by the administration of activated charcoal. Complications include aspiration and direct administration of charcoal into the lung.¹¹

Because activated charcoal is an inert substance, it is thought that lung injury after aspiration of activated charcoal is caused by gastric

contents. Aspiration of gastric contents causes neutrophils to release neutrophil elastase, which increases pulmonary vascular permeability.¹³ In comparison, intratracheal administration of activated charcoal does not increase elastase in the bronchoalveolar fluid.¹⁴ Activated charcoal can activate alveolar macrophages, which are a potent source of oxygen radicals, proteases, and other inflammatory mediators. Charcoal also causes obstruction of small distal airways. Overdistention of alveolar segments in areas not occluded by charcoal leads to volutrauma in those areas, which increases microvascular permeability.¹⁵ Although case reports reveal long-term pulmonary pathology after aspiration or instillation of activated charcoal,^{16,17} the true incidence of chronic problems after charcoal aspiration is unknown.

Cathartics

Administration of a cathartic alone has no role in the management of poisoned patients. Routine use of a cathartic in combination with activated charcoal is not endorsed.¹⁸

Whole-Bowel Irrigation

Whole-bowel irrigation consists of administration through a nasogastric tube of an osmotically balanced, polyethylene glycol–based electrolyte solution to decontaminate the entire gastrointestinal tract by physically expelling intraluminal contents. As much as 1500 to 2000 mL/h can be administered to an “awake” adult patient. Negotiation to let the patient attempt to drink the solution only causes delay, because patients are unable to drink at a constant rate. Whole-bowel irrigation should not be used routinely in the poisoned patient. However, it can be considered for potentially toxic ingestions of sustained-release or enteric-coated drugs and for drugs not likely to be adsorbed to activated charcoal (iron, lithium, potassium) and for the removal of illicit drug packets.¹⁹ Contraindications include bowel pathology, unprotected or compromised airway, hemodynamic instability, and intractable vomiting. Complications are nausea, vomiting, and abdominal cramps.¹⁹

Clinical Implications of Gastrointestinal Decontamination

There is no role for syrup of ipecac in the hospital setting. Gastric lavage may be considered for obtunded patients if it can be instituted within 1 hour after the ingestion. Single-dose activated charcoal should not be routinely administered to patients with mild to moderate degrees of poisoning. Whole-bowel irrigation should be considered for awake patients within the first hours after ingestion of a sustained-release preparation, ionic compounds (e.g., lithium), or packets of illicit drugs.

These guidelines refer to the routine management of poisoned patients. Cellular toxins require special consideration. The physician should always call the Poison Center (1-800-222-1222 in the United States) to discuss a patient with an ingestion and to seek further guidance on management.

ENHANCED ELIMINATION

Multiple-Dose Activated Charcoal

Multiple-dose activated charcoal is the repeated oral administration of activated charcoal to enhance drug elimination. If the drug concentration in the gut is lower than that in the blood, the drug will passively diffuse back into the gut. The concentration gradient, intestinal surface area, permeability, and blood flow determine the degree of passive diffusion. As the drug passes continuously into the gut, it is adsorbed onto the charcoal particles, a process called *gastrointestinal dialysis*. Multiple-dose activated charcoal also interrupts the enterohepatic and enterogastric circulation of drugs. Drugs with a prolonged elimination half-life, a small volume of distribution (less than 1 L/kg), and little

protein binding are the most amenable to this sort of management.²⁰ Multiple-dose activated charcoal should be considered if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline. With all of these drugs, data confirm enhanced elimination, although no controlled studies have demonstrated clinical benefit.²⁰ Other ingestions may benefit from multiple-dose activated charcoal, but there are insufficient clinical data to routinely recommend its use.

The initial dose of charcoal is 50 to 100 g, and this treatment is followed every 1, 2, or 4 hours by a dose equivalent to 12.5 g/h. More frequent, smaller doses may prevent vomiting. Multiple-dose activated charcoal can be continued until the patient improves clinically. Contraindications include an unprotected airway, intestinal obstruction, and an anatomically abnormal gastrointestinal tract. Complications include bowel obstruction and vomiting with subsequent aspiration.²⁰

Urinary Alkalinization

Urinary alkalinization is the administration of intravenous (IV) sodium bicarbonate to produce urine with a pH \geq 7.5. The objective of treatment is pH manipulation, not forced diuresis. Hypokalemia is the most common complication. Alkalemia also can occur.²¹ Urinary alkalinization should be considered as first-line treatment in patients with moderately severe salicylate poisoning who do not meet the criteria for hemodialysis. Urinary alkalinization also should be considered for patients with severe poisoning due to 2,4-dichlorophenoxyacetic acid or mecoprop (MCP) poisoning. Urinary alkalinization is not recommended as first-line treatment for cases of phenobarbital poisoning, because multiple-dose activated charcoal is superior.²¹

SELECTED ANTIDOTES

Stabilization of the patient always should precede administration of antidote(s). The effects of the toxin can outlast the effects of the administered antidote. Patients receiving antidotes should be observed in a critical care setting.

Dextrose

Up to 8% of patients with altered mental status are hypoglycemic.²² Hypoglycemia can be a result of drug or toxin exposure, nutritional deprivation, or a medical complication (e.g., sepsis, hyperthermia). Glucose should be checked at the bedside for all patients with altered mental status.

Naloxone

Endogenous and exogenous opiates produce their effects by binding at one or more opiate receptors. Naloxone, nalmefene, and naltrexone are competitive opioid antagonists that bind at the mu (μ), kappa (κ), and delta (δ) receptors and competitively prevent the binding of endogenous and exogenous opiates at these receptors. The duration of action of naloxone is 15 to 90 minutes. Its clinical effects depend on the dose and route of naloxone administration as well as the dose and rate of elimination of the opiate agonist. Naloxone can be administered by IV, intramuscular, intratracheal, or sublingual routes. After IV administration, naloxone rapidly enters the central nervous system (CNS). In patients with opioid poisoning, respiration improves within 1 to 2 minutes, and consciousness is restored. The goal of naloxone administration is to restore respiratory function. Miosis, inhibition of baroreceptor reflexes, laryngospasm, and decreased gastrointestinal motility are also reversed.²³

Certain nonopiate drugs can cause release of endogenous opiates, contributing to CNS and respiratory depression as well as hypotension. Alternatively, nonopiate drugs and naloxone can compete for an unidentified nonopiate receptor that contributes to CNS depression and hypotension. Naloxone can reverse the toxicity caused by drugs that are not opioids, such as clonidine, angiotensin-converting enzyme

inhibitors, and sodium valproate. Naloxone should be administered to all patients with altered mental status or coma of unknown cause. Opioid-dependent patients should receive only small doses in an effort to restore respiratory function and prevent rapid withdrawal. If a patient is not opioid dependent, a reasonable starting dose is 2 mg, increasing to 10 mg (in increments) if there is no response. Large doses of naloxone may be necessary to reverse the effects of nonopioid drugs or of opioid drugs with high affinity for the δ and κ opiate receptors.

If respiratory depression returns, the initial dose of naloxone may have to be repeated or a constant infusion of naloxone initiated. The starting dose for a constant infusion of naloxone is hourly administration of about one-half to two-thirds of the bolus dose that reversed the opioid effects. If withdrawal is precipitated, it is short lived and not life-threatening. Complications of naloxone administration are very rare.²⁴

Flumazenil

Flumazenil competitively antagonizes the pharmacologic effects of drugs that act on the benzodiazepine receptor (e.g., all drugs in the benzodiazepine class). Receptor occupancy follows the law of mass action, and antagonism is dose dependent. The duration of action of flumazenil is variable and depends on the type of benzodiazepine ingested, relative doses of agonist and antagonist, presence of ongoing benzodiazepine absorption, and relative receptor binding affinities. Flumazenil also antagonizes the sedative effects of drugs other than benzodiazepines, such as zolpidem (Ambien), cannabis, ethanol, promethazine, chlorzoxazone, and carisoprodol. These drugs may have differing affinities for the γ -aminobutyric acid A (GABA_A) receptor, implying that the dose of flumazenil required to reverse the effects depends on the affinity of the specific drug for the receptor.²⁵

Flumazenil is safe and effective for reversing conscious sedation after short procedures such as endoscopy. This safety has been generalized to imply that flumazenil also is safe for patients with a multidrug overdose and that reversal of benzodiazepine-induced sedation prevents morbidity from procedures such as endotracheal intubation or computed tomography. However, many patients have experienced single or multiple seizures after flumazenil administration. Status epilepticus has been precipitated, leading to death. The data are insufficient to determine whether morbidity or mortality is increased as a result of flumazenil-precipitated seizures.^{26,27}

Flumazenil administration can precipitate seizures in patients with an overdose who have ingested both a benzodiazepine and a proconvulsant drug or just a proconvulsant drug. Flumazenil also can precipitate seizures in patients who have a history of seizures, chronic benzodiazepine ingestion, or head injury. Identification of patients at risk for seizures is difficult.²⁸ Before administering flumazenil to a patient with a benzodiazepine ingestion, it is reasonable to first obtain an electrocardiogram (to rule out exposure to proconvulsant tricyclic antidepressants) and a urine drug screen. Resedation occurs after 18 to 120 minutes in approximately half of patients awakened by flumazenil. Therefore, either continuous IV infusion or observation for a number of hours is required.²⁹

Administration of flumazenil to patients with an overdose should not be routine. It should be limited to the following situations: iatrogenic overdose with known patient history, obtundation in a toddler secondary to ingestion of benzodiazepine, and reversal of a paradoxical response to benzodiazepine.

Physostigmine

Physostigmine inhibits acetylcholinesterase, the enzyme responsible for the metabolism of acetylcholine (ACH). ACH is an endogenous neurotransmitter that mediates action by binding to muscarinic and nicotinic receptors. Accumulation of ACH stimulates cholinergic nerve endings. In the poisoned patient, physostigmine is most frequently administered to treat anticholinergic toxicity. Clinical signs of anticholinergic toxicity are recognized by the mnemonic, "Blind as a bat, Red as a beet, Hot as a hare, Dry as a bone, Mad as a hatter" (see

Table 153-1). Physostigmine administration should be considered if life-threatening clinical signs of anticholinergic peripheral effects (hypertension, tachycardia, and seizures) or central effects (painful psychosis) are present. However, it is extremely difficult to balance cholinergic and anticholinergic forces. Complications of cholinergic crises (caused by excessive doses of physostigmine) include hypertension, dysrhythmia, asystole, bronchorrhea, bronchoconstriction, seizures, and status epilepticus. Contraindications to physostigmine administration include bradycardia and conduction delays, reactive airway disease, peripheral vascular disease, intestinal or bladder obstruction, and treatment with a depolarizing neuromuscular blocking agent (e.g., succinylcholine). An acceptable dose of physostigmine is 1 to 2 mg IV over 10 minutes. This drug should be administered in the presence of a physician because of the potential for precipitation of life-threatening cholinergic effects.³⁰

HYPOTENSION IN THE POISONED PATIENT

Hypotension in the poisoned patient is most frequently caused by receptor blockade, drug-induced myocardial depression, or drug-induced vasodilatation. Clinicians reflexively initially treat hypotension by infusing IV fluids; however, unless the poisoned patient is hypovolemic, large volumes of fluid can predispose patients to the development of acute respiratory failure.

Catecholamines are the pressors of choice for treatment of hypotension in most intensive care unit (ICU) patients who are older, chronically ill, or acutely ill from an infectious process. The causative factors in sepsis-induced vasodilation and myocardial depression/ischemia are different from the factors that cause drug-induced vasodilation, myocardial depression, or ischemia. Treatment approaches must address the cause of the hypotension and not assume that all hypotensive patients should be treated in a similar manner.

Poisoned patients who are young and healthy respond to hypotension with an outpouring of endogenous catecholamines. Adrenergic receptors are sensitive in young patients. Administration of exogenous catecholamines is unlikely to be of much benefit, because catecholamine receptors are already maximally stimulated by endogenous catecholamines. Agents that must be considered for the treatment of hypotension in the poisoned patient are sodium bicarbonate (for a sodium channel-blocking agent), glucagon, and insulin/glucose.

Glucagon

The cardiovascular effects of glucagon are mediated by myocardial glucagon receptors that are catecholamine independent. Stimulation activates adenylate cyclase, leading to increased intracellular levels of the second messenger, cyclic adenosine monophosphate (cAMP). This cyclic nucleotide increases myocardial calcium uptake. Both the slope of phase zero of the action potential and the conduction velocity through the atrioventricular node are increased. Glucagon increases heart rate and stroke volume, thereby increasing cardiac output. After IV administration, augmented inotropy is seen within 1 to 3 minutes, with a peak effect in 5 to 7 minutes.³¹

Glucagon should be considered early in the treatment of hypotensive poisoned patients, especially those patients with beta-adrenergic antagonist toxicity. Treatment regimens vary. An acceptable regimen is 10 mg of glucagon given over 10 minutes (rapid administration causes vomiting), followed by 1 to 3 mg/h. If the patient wretches, the hourly dose of glucagon should be decreased. Elderly patients may be more sensitive to the emetic effects of the drug.

Insulin and Glucose

Insulin improves contractility in anoxic rat hearts and improves cardiac index after cardiopulmonary bypass surgery. During drug-induced shock, insulin shifts myocardial fatty acid oxidation to carbohydrate oxidation, which increases contractility, left ventricular

pressure, and rate of change of developed pressure. Enhanced fatty acid oxidation, such as occurs after epinephrine administration, transiently increases contractility at the expense of increased myocardial oxygen consumption.³²

Insulin and glucose treatment in poisoned patients is commonly referred to as high-dose insulin-euglycemia therapy (HIET). Insulin can be bolused at 0.5 to 1 U/kg, followed by an infusion at 0.5 to 1 U/kg/h.³³ The infusion can be titrated up to improve inotropy and contractility and to increase blood pressure. Case reports have had safe outcomes with large bolus and infusion doses.³³ Concurrent administration of glucose is used to maintain euglycemia. Hourly serum glucose checks are mandatory because hypoglycemia occurs frequently. Potassium should also be monitored due to intracellular shift.

CARDIAC ARRHYTHMIAS

ICU treatment regimens assume that a diseased heart is the cause of most cardiac arrhythmias. This assumption is invalid in poisoned patients. Treatment of the arrhythmia must take into consideration the pharmacology of the toxin causing the arrhythmia.

ACUTE RENAL FAILURE

In poisoned patients, acute renal failure (ARF) is most frequently the result of a decrease in extracellular fluid volume and renal hypoperfusion caused by drug- or chemical-induced vasodilation, drug-induced myocardial depression, or rhabdomyolysis. Attempts to prevent ARF are important because there is no specific therapy once ARF is established. Studies evaluating the efficacy of low-dose dopamine (0.5–3.0 mg/kg/min) in preventing ARF have not demonstrated any benefit, but the patient populations in these studies consisted of critically ill patients with established ARF or at high risk for developing ARF.³⁴ The efficacy of administration of low-dose dopamine after periods of hypotension in poisoned patients who typically are younger and without chronic disease has not been evaluated. When dopamine is administered to normal human subjects, there is a dose-dependent increase in renal blood flow, sodium excretion, and glomerular filtration rate.³⁵ Low-dose dopamine also limits adenosine triphosphate (ATP) utilization and oxygen requirements in nephron segments at risk for ischemia.³⁶ Although there are no studies regarding the efficacy of low-dose dopamine in cases of drug-induced hypotension, one may consider administration in previously healthy poisoned patients who have adequate vascular volume and remain oliguric or anuric despite maximal diuretic therapy.

SEIZURES

Blood pH can be as low as 7.17 at 30 minutes and 7.20 at 60 minutes after resolution of a 30- to 60-second seizure.³⁷ Acidosis decreases cardiac output, oxygen extraction, and left ventricular end-diastolic pressure and impairs myocardial contractility. If a patient has ingested a cardiotoxic drug (e.g., a tricyclic antidepressant) that causes significant myocardial depression, the consequences of acidosis can increase the toxicity of the drug. Ictal increases in plasma epinephrine levels can add to the potential risk for cardiac arrhythmias. Additionally,

airway reflexes are inhibited postictally, which adds to the potential for aspiration.³⁸

Whether seizures increase morbidity and mortality in poisoned patients is difficult to ascertain. Deaths of poisoned patients who sustain seizures are usually attributed to the toxicity of the drug. Because of the number of variables, it is impossible to know whether the risk for mortality is influenced by the presence of convulsions. Accordingly, the physician should take an aggressive approach toward terminating seizures in poisoned patients. Benzodiazepines are the drugs of choice to quickly terminate seizures because they are lipophilic and rapidly enter the CNS.

MECHANICAL VENTILATION AND EXTUBATION

Endotracheal intubation is commonly indicated for the management of poisoned patients on the basis of respiratory depression or impaired protective airway reflexes or both. As the drug is metabolized, its effects abate, and the patient's sensorium improves. The patient may become alert slowly or very suddenly. The patient should be extubated if ability to protect the airway is evident and ventilation is adequate for 15 to 60 minutes with minimal respiratory support (e.g., 5-cm H₂O positive end-expiratory pressure and 5-cm H₂O pressure support). Unnecessary or excessive administration of sedatives or anxiolytics in an attempt to make the patient more comfortable can delay weaning from mechanical ventilation and extubation and increase the risk for complications.

KEY POINTS

1. The theory of gastric decontamination is that removal of toxins from the stomach (where absorption is poor) before they move into the small intestine (where absorption is more rapid) decreases the toxicity of the poisoning.
2. Stabilization of the patient should always precede administration of antidote(s). The effects of the toxin can outlast the effects of the administered antidote. Patients receiving antidotes should be observed in a critical care setting.
3. Treating hypotensive, poisoned patients with large volumes of intravenous fluids can increase the risk for acute respiratory failure.
4. Efforts to prevent development of acute renal failure (ARF) in the poisoned patient are important because there is no specific therapy once ARF is established.
5. An aggressive approach should be taken toward terminating seizures in the poisoned patient. Benzodiazepines are the drugs of choice to quickly terminate seizures, because they are lipophilic and rapidly enter the central nervous system (CNS).
6. The clinical value of analytic toxicology testing depends on the clinician's ability to understand and interpret the results.

Balock's fundamental work on shock showed that injury precipitated obligatory local and regional fluid losses, the effects of which could be ameliorated by vigorous restoration of intravascular volume. This concept became a cornerstone to the understanding of the pathophysiology of shock and provided the fundamental rationale for IV therapy for hemorrhage and hypovolemia.¹

The introduction of blood transfusions as the result of contributions by surgeons during World War I and World War II dramatically changed outcomes in cases of severe hemorrhage. During the Korean War, fluid overload became a common and lethal side effect of resuscitation, owing to a lack of knowledge about how infusates disperse and are eliminated during trauma. Between the Korean War and the Vietnam War, Shires and colleagues described the shifts of fluid and electrolytes into cells after severe hemorrhagic shock. As a consequence, treatment of patients with shock was altered during the Vietnam War, leading to better outcomes and a lower incidence of acute renal failure. It has taken two more wars since 911 to return to the basic concept that patients who lose whole blood should be given whole blood or at least the right ratio of blood's main components, plasma, platelets, and red cells as early as possible.^{2,3}

Mechanisms of injury and severity of blood loss as well as prehospital interventions vary widely among trauma centers worldwide. The number of preventable deaths due to hemorrhage are still significant. Therefore, prompt and definitive control of hemorrhage and innovative resuscitative strategies continue to be the cornerstone of treatment.⁴

RESUSCITATIVE STRATEGIES IN HEMORRHAGIC SHOCK

The mainstays of therapy in hemorrhagic shock are bleeding control, tissue oxygenation, coagulation support, and maintenance of normothermia.⁵ Fluid resuscitation strategies in prehospital and hospital settings are important.

Vascular Access for Patients with Severe Hemorrhage

In the trauma patient presenting with multiple serious injuries and hemorrhagic shock, vascular access is necessary. Venous access should never be initiated on an injured limb. When thoracoabdominal injury is suspected, it is prudent to obtain infradiaphragmatic and supradiaphragmatic access.

Advanced trauma life support (ATLS) guidelines recommend rapid placement of two large-bore (16 gauge or larger) IV catheters. The most suitable veins are at the wrist, on the dorsum of the hand, at the antecubital fossa in the arm, and on the saphenous in the leg. If peripheral IV catheters are unable to be placed, catheters can be placed in the central veins. The femoral vein is the most frequent central vein cannulated. The subclavian vein is another alternative and can be placed safely in experienced hands. The internal jugular vein is rarely used in trauma patients because of the possibility of cervical spine injuries and the need for cervical immobilization with a collar. Patients with absent pulses may need to undergo cutdown to cannulate the femoral vein under direct vision to obtain IV access. Currently, prehospital personnel are well trained to use intraosseous (IO) needles. It is a technique best applied under difficult circumstances such as in a

moving environment, in the helicopter, or on poor roads. IO needles are now standard practice for trauma care in many prehospital settings. This technique is taught easily, and clinical competencies are acquired rapidly. IO lines allow for the use of medication and blood transfusion if necessary in desperate cases.^{6,7} IO access is increasingly being used in the emergency department when peripheral lines cannot be obtained and hypovolemia makes central vein cannulation difficult.

Resuscitative Fluids and Interventions

Prehospital Fluid Resuscitation

There are several recent studies currently undertaken to evaluate the effectiveness of prehospital use of plasma, packed red blood cells (PRBC), and whole blood. The use of PRBC in the prehospital setting was independently associated with a lower risk of 24-hour mortality, 30-day mortality, and trauma-induced coagulopathy in severely injured patients with blunt trauma. Early resuscitation incorporating PRBC transfusion initiated before arrival of the patient at the trauma center without a delay in transport was associated with improved outcomes.⁸ Two additional studies are also being completed to test the efficacy of administering thawed plasma in the helicopter and the role of using prehospital administration of tranexamic acid (TXA).^{9,10}

The Prehospital Air Medical Plasma (PAMPer) trial is aimed at determining the effect of prehospital plasma transfusion during air medical transport on 30-day mortality in patients at risk for traumatic hemorrhage. This study is a multicenter, cluster-randomized clinical trial. The trial will enroll trauma patients with profound hypotension (SBP \leq 70 mm Hg) or hypotension (SBP 71-90 mm Hg) and tachycardia (HR \geq 108 bpm) from six level I trauma center air medical transport programs. This trial is one of three awards funded by the Department of Defense (DoD) to investigate prehospital plasma transfusion in traumatic shock. The Control of Major Bleeding after Trauma (COMBAT) trial will assess the effect of ground ambulance plasma administration, looking at the effect on trauma-induced coagulopathy (TIC), transfusion requirements, metabolic recovery, organ failure, and mortality.¹¹ The Prehospital Use of Plasma for Traumatic Hemorrhage (PUPTH) trial will also examine the impact of using thawed prehospital plasma on mortality and coagulopathy.¹²

Tranexamic Acid for Trauma Patients

A recently published landmark trial that studied the safety and efficacy of tranexamic acid (TXA) deserves special attention. This is a clinical randomization of the use of an antifibrinolytic agent in significant hemorrhage (CRASH-2) in trauma resuscitation. The results of this trial showed that use of TXA resulted in a reduction in all-cause mortality and death as a result of bleeding. This study was performed in a rigorous manner that reflected real-world clinical practice across a wide variety of settings, including austere environments. CRASH-2 provides level I evidence for the use of TXA to reduce mortality in trauma patients. The inclusion criteria for this study were clinical, not laboratory based, and very broad. As a result, the population truly at risk for hemorrhagic death was much smaller than the overall study population, as further evidenced by the fact that slightly fewer than 50% of patients in each arm underwent surgical interventions. The fact that a significant reduction in death as a result of hemorrhage was observed is therefore even more remarkable and suggests an important

treatment effect in critically injured patients with a risk of bleeding.¹³ Further testing is warranted before this should become standard of care.

Trauma-Induced Coagulopathy, Coagulation Factors, and Platelets

Severe bleeding, surgery, and massive transfusion interact synergistically to lead to the lethal triad: hypothermia, acidosis, and coagulopathy. Coagulopathy promotes bleeding and hypotension, which leads to hypothermia and acidosis. Hypothermia and acidosis impair thrombin generation and decrease fibrinogen levels.¹⁴

Failure of coagulation in trauma is multifactorial and is characterized by the combined presence of coagulation abnormalities resembling disseminated intravascular coagulation (DIC), excessive fibrinolysis (likely caused by release of tissue plasminogen activator [TPA] from damaged tissues), dilutional coagulopathy due to excessive fluid treatment, and massive transfusion syndrome resulting in dilution of coagulation factors and platelets.¹⁵

Until recently, coagulopathy associated with trauma was thought to be a secondary phenomenon resulting mainly from loss of coagulation factors during hemorrhage and dilution from resuscitation fluids. However, there is strong evidence showing that there is an early almost immediate trauma-induced coagulopathy (TIC) that occurs within minutes of injury and is associated with a fourfold increase in mortality.¹⁶ This is a multifactorial phenomenon partly due to an endogenous coagulopathy that occurs as a result of tissue damage in severe shock. The more we learn about TIC, the more we realize that it is a complex multifactorial event. The severity of trauma correlates with the degree of the coagulopathy, however; standard coagulation tests fail to adequately describe the complex processes occurring in TIC and thus have limited value. There is a lack of agreement about the clinical definition, and currently there are no operational scales that could aid in a clinical classification that covers a rational spectrum of bleeding abnormalities after injury.¹⁷ Many alterations have been described, including activation of protein C as well as autoheparinization following glycocalyx disruption as important instigators of TIC, but fibrinogen depletion and platelet dysfunction must also be taken into account to fully treat the hemorrhagic process. In addition to all these challenges, the event *per se* is very dynamic and can occur in a short time, thus precluding the use of time-consuming and cumbersome coagulation tests that are usually being measured at the same time that TIC is being aggressively treated.

The role that platelets play in TIC is difficult to elucidate, in part due to the fact that classic plasma-based clotting test do not assess platelet function, and light transmittance aggregometry, considered a gold standard for platelet function, is both labor intensive and time consuming. Extensive ADP metabolism secondary to endothelial cell injury in combination with “platelet exhaustion” due to overwhelming immediate activation may be all factors that generate platelet dysfunction in early trauma. A prolonged refractory state could explain why platelet counts often remain in a normal range despite being dysfunctional.

These difficulties have led to a renewed interest in the use of thromboelastography (TEG)—a point of care assessment of clot generation, strength, and breakdown. This procedure has the potential to provide a rapid assessment of the whole clotting process, but it requires further validation in the acute setting. In the absence of a validated diagnostic test at the point of care, management is therefore blind to the status of the coagulation system and relies on clinical judgment and empiric therapy.¹⁸

A recent prospective observational multicenter study using TEG and platelet mapping in 51 trauma patients showed that platelets were inhibited in 86.1% of trauma patients, compared to 4.2% in healthy volunteers using as an activator.¹⁹ Patients with a high base deficit also had worse platelet inhibition.

The clinical importance of platelet inhibition after trauma is significant. Close to 45.5% of critically injured patients had “platelet hypo-

function” upon admission, and 91.1% experienced dysfunction during their ICU stay. Twenty-four-hour and in-hospital mortality was significantly higher: up to tenfold increase in 24-h mortality with platelet hypofunction.²⁰

Despite our lack of complete understanding of the TIC phenomenon it is clear that a systematic approach to resuscitation must include early management, rapid scene-to-hospital transport, swift hemorrhage control (including surgical intervention, interventional radiology, or innovative balloon occlusive techniques such as resuscitative endovascular balloon occlusion of the aorta (REBOA²¹), and the avoidance of excessive crystalloid resuscitation. Existing pharmaceutical treatments such as TXA may become a standard of care and if used should be administered very early after trauma. Trauma centers and hospitals caring for injured patients need to develop and institute standard protocols for diagnosing and treating this early manifestation of trauma.

TIC and the need to administer a massive transfusion protocol are two concepts inexorably linked to the management of severe hemorrhage. Predictive scores to determine the need for massive transfusion have been recently proposed. The ABC (Assessment of Blood Consumption) score accounts for four dichotomous components that are easily obtained at the bedside for early evaluation of injured patients. The presence of any one component contributes one point to the total score for a possible range of scores from 0 to 4. Parameters include penetrating mechanism (0 = no, 1 = yes); emergency department systolic blood pressure of 90 mm Hg or less (0 = no, 1 = yes); emergency department heart rate of 120 beats/min or greater (0 = no, 1 = yes); and positive abdominal sonogram (0 = no, 1 = yes).

The ABC score was validated in a multicenter study and yielded a predictive value consistent across several trauma centers examined. The negative predictive value was 97%, and less than 5% of patients who will require massive transfusion will be missed using the ABC score.^{22,23}

Most recently, a quantitative scoring system for TIC and a clinical outcomes definition for postinjury mortality due to coagulopathy have been proposed. This classification offers standardized clinical scoring and death criteria in patients with TIC and should be useful for research in TIC, ultimately leading to an improvement in patient outcome.¹⁷

Red Cells, Platelets, and Plasma—the Ideal Ratio and the Prospects of Whole Blood Resuscitation

Only after the implementation of radical changes in blood banking practice in the early 70s that imposed the usage of separate components of blood in transfusion medicine, the use of whole blood was historically the gold standard for treating hemorrhagic shock during military conflicts.²⁴ After the recent experience in the Middle East, the main principles of current resuscitation strategies has now shifted toward preventing or reversing the effects of coagulopathy by means of using a balanced ratio of whole blood's main components as early as possible (1:1:1—plasma: packed red blood cells: platelets).²

This combination approach is referred to as *whole blood-like* resuscitation despite being suboptimal from a compositional when compared to whole blood.^{25,26} The use of whole blood continues to increase across trauma centers in the United States and is thought to provide the bleeding patient the identical components he or she is losing while maximizing the resuscitative and hemostatic effects.^{27,28}

Additional benefits may include minimization of donor exposure, as the requirements for whole blood storage and resuscitation would lower overall age of the transfused products as compared to balanced component resuscitation.

While the use of whole blood is researched and eventually generalized, current available options are type O-negative, type-specific, typed and screened, or typed and cross-matched packed red blood cells. The initial choice depends on the degree of hemodynamic instability. Type O-negative red cells have no major antigens and can be used safely for patients with any blood type. Unfortunately, only 8% of the population has O-negative blood, and blood bank reserves for O-negative blood

are low. O-positive blood can be used in male patients but may be a problem in female Rh-negative patients.

Early identification of severe injuries with the likelihood of hemorrhage should suffice for the trauma team leader to alert the blood bank. Hematocrit levels should not guide the decision for transfusion in acute hemorrhage. Protocols for massive transfusion should be established, and the blood bank should automatically begin preparation of fresh frozen plasma and platelet packs if massive bleeding is anticipated.

If 50% to 75% of the patient's blood volume has been replaced with type O blood, one should continue to administer type O red cells. Otherwise, the risk of a major cross-match reaction increases, since the patient may have received enough anti-A or anti-B antibodies to precipitate hemolysis if A, B, or AB units are subsequently given. Obtaining type-specific red cells requires 5 to 10 minutes in most institutions.

When blood is typed and screened, the patient's blood group is identified, and the serum is screened for major blood group antibodies. A full cross-match generally requires about 45 minutes and involves mixing donor cells with recipient serum to rule out antigen/antibody reactions.

Massive transfusion protocols have been developed and utilized in major trauma centers. Activating the massive transfusion protocol gives a fixed ratio of red cells to plasma to platelets. High plasma- and platelet-to-red cell ratio has been shown to increase survival in retrospective studies.²⁹ Military data showed an increase in survival with a red cell-to-plasma ratio approaching 1:1.³⁰ Civilian trauma centers are increasingly adopting a 1:1:1 ratio for massive transfusion protocols. The Prospective Observational Multicenter Major Trauma Transfusion (PROMMTT) study demonstrated that clinicians were transfusing patients with a blood product ratio of 1:1:1 or 1:1:2 and that early transfusion of plasma (within minutes of arrival to a trauma center) was associated with improved 6-hour survival after admission.^{31,32}

In 2015, the first multicenter, randomized clinical trial was completed in order to address the effectiveness and safety of a 1:1:1 transfusion ratio compared with a 1:1:2 transfusion ratio in patients with trauma who were predicted to receive a massive transfusion. The Pragmatic, Randomized Optimal Platelet and Plasma Ratios (PROPPR) trial showed that in patients with severe trauma and major bleeding,

early administration of plasma, platelets, and RBCs in a 1:1:1 ratio compared with a 1:1:2 ratio did not result in significant differences in mortality at 24 hours or at 30 days. However, more patients in the 1:1:1 group achieved hemostasis, and fewer experienced death due to exsanguination by 24 hours. As expected, though there was an increased use of plasma and platelets transfused in the 1:1:1 group, no other safety differences were identified between the two groups.³³

Putting It All Together: A Comprehensive Approach for Management of Shock and Severe Bleeding

Resuscitation management should start at the very moment that the patient is found at the scene. The use of tourniquets must be liberal and competencies for proper application by EMT personnel should be part of all EMS systems. Hemostatic dressings and hypotensive resuscitation must also be available in the prehospital setting.

If possible, a balanced blood product transfusion should be initiated early; ideally providing thawed plasma and PRBCs. Once the patient arrives to the trauma center, TEG, hemoglobin, and a venous blood gas are immediately obtained.

Patients in shock or hypotensive or with an ABC score >2 should be signaled as candidates for a massive transfusion. Initially they must receive blood components in a 1:1:1 ratio. Need for surgery or angio-embolization is determined soon and implemented immediately. At this point, it is critical to assess the effectiveness of the resuscitative interventions, and therefore, conversion to a goal-driven management of TIC is warranted in order to specifically manage the impaired coagulation depicted by rapid TEG. It is imperative to reduce to a minimum the use of crystalloids and artificial colloids. TXA should be infused early in those patients with TEG evidence of fibrinolysis.

Damage control and staged procedures must be carefully planned, and multidisciplinary communication with the ICU team and other consultants is key in maintaining the proper order of priorities and in the implementation of ancillary care. Measured and titrated fluid administration will aid in securing definitive facial closure of patients with open abdomen undergoing damage control. It is fundamental to exercise an individual assessment of the patient and his or her response to therapy and adjust all resuscitative options throughout this critical early stage.

Mediastinitis includes a variety of thoracic infections that occur in the space between the sternum and the spine, above the diaphragm, and below the thoracic outlet. The diagnosis, treatment, and prognosis of mediastinitis are determined by their location and etiology. The mediastinum can be divided anatomically into superior and inferior compartments at the sternal angle, the inferior with further division into three clinically relevant compartments: anterior (between the posterior sternum and the anterior pericardium), middle (the intrapericardial contents), and posterior (bounded anteriorly by the posterior pericardium and posteriorly by the spine). The pleural cavities are the lateral boundaries for each of these mediastinal spaces (Fig. 155-1).

With respect to etiology, mediastinitis can be either primary, arising without prior intervention, or secondary, occurring post intervention. Clinically, the anatomic anterior and middle compartments can be considered together, as mediastinitis occurs most commonly in those combined spaces secondarily as a postoperative complication of cardiac operations.

Esophageal pathology accounts for the overwhelming majority of the mediastinal infections of the posterior compartment.

Other more unusual forms of mediastinal infections or inflammation include those that migrate into the mediastinum from adjacent fascially contiguous spaces and those that are more indolent than acute and are characterized by chronic inflammation and fibrosis.

Accordingly, this presentation of the subject will follow these anatomic and etiologic distinctions: acute anterior mediastinitis, acute posterior mediastinitis, and migratory and chronic mediastinal inflammation.

■ ACUTE ANTERIOR MEDIASTINITIS

The most common form of acute anterior mediastinitis is that occurring after sternotomy for a cardiac operation. Rarely, it may occur after traumatic sternal fracture¹ or following descending cervical infections.

The term *mediastinitis* after cardiac operations should strictly refer to an infection involving the space deep to the sternum. Other forms of postoperative infection can be identified as superficial sternal wound infection (SWI; above the fascia without sternal involvement) and sternal osteomyelitis (without deeper infection).

As no impervious anatomic barrier exists between the posterior cortex of the sternum and the space behind it, any infection posterior to the sternum is considered an infection of the anterior mediastinum.

Clinically, especially in more obese patients, it is sometimes unclear as to whether one is initially dealing with a superficial problem (anterior to the fascia), a sterile dehiscence, or a deeper infection. More than a small amount of drainage, any sternal instability, or evidence of separation suggest at least a sterile dehiscence and the need for re-exploration, deep cultures, and appropriate reclosure.

Incidence, Pathology, and Prevention

Over the past 2 decades, there may be a trend toward lower reported rates of mediastinitis after sternotomy (more large series with <1%

incidence); however, the reported range remains wide, from 0.24% to 4% of cardiac operations, due in part to the various definitions of mediastinitis itself.^{2,3,4} Increasingly, as the postoperative length of stay decreases, mediastinal infections are diagnosed days or even months after hospital discharge, with the median time to diagnosis variously reported at around 10 days after surgery.

A number of host factors that increase the risk of post-cardiac surgery mediastinitis have been identified. Among these are diabetes, increased body mass index, older age, renal failure, prolonged preoperative hospitalization, immunosuppression, chronic obstructive pulmonary disease, cigarette smoking, reoperation, preoperative atrial fibrillation, and elevated C-reactive protein.^{3,5-7}

An increased incidence of deep SWI (DSWI) or dehiscence has been associated with intraoperative factors such as bilateral internal mammary use (5% versus 1% in most series), off-midline sternotomy, prolonged operative time, and the use of an intraaortic balloon pump.⁷

In multiple studies, bone healing was significantly impaired by using bone wax for sternal hemostasis when compared with water-soluble polymer wax, suggesting the use of the latter as a useful alternative, since bone healing immediately postoperatively is the most critical time frame for the prevention of sternal nonunion and infection.⁸

In high-risk patients, sternal closure with rigid plate fixation showed a significant decrease in the incidence of postoperative mediastinitis when compared to a similar population of patients whose sterna were closed with wire, as reported by Songa et al.⁹

Furthermore, several studies have shown that the use of cyanoacrylate glue decreases the infection rates of deep surgical and superficial surgical sites in patients who have sternal detachment or are at high risk for developing infection.¹⁰

Postoperatively, increased glucose levels (>200 mg/dL),¹¹ re-exploration, and prolonged ventilator use are associated with a higher incidence of deep sternal infection.⁷ Glucose values as low as ≥130 mg/dL have been linked to such infection in children.¹²

Avoiding sternotomy entirely, as can be done with less chest wall-invasive approaches, appears to dramatically reduce or eliminate the risk of mediastinal infection after cardiac operations.⁷

Postoperative tracheostomy is required in some poststernotomy patients, and many of these have some of the risk factors that are also predictive of DSWI. Early tracheostomy for patients with prolonged ventilator dependence, once deferred 2 or more weeks after sternotomy for fear of contaminating the anterior mediastinal space, has not been shown to be associated with an increased incidence of mediastinitis (mean of 5.6 days post cardiac operation).¹³ Tracheostomy per se is not a risk factor for DSWI, whereas it serves as a surrogate for respiratory failure.^{14,15} Specifically, the technique of percutaneous tracheostomy has not been associated with a subsequent increase in mediastinal infection.¹⁶

Staphylococcal species are the most common organisms seen in patients with poststernotomy deep wound infection, and these are increasingly methicillin resistant.¹⁷ Coagulase-negative resistant organisms are more common in patients who have prolonged hospitalizations.¹⁸ Gram-negative organisms may be cultured, particularly from diabetics, in patients with gram-negative pneumonia prior to operation or in those who require re-exploration.¹⁹

Given the most common organisms causing these infections, a second-generation cephalosporin is still the most accepted preoperative prophylaxis. Vancomycin is substituted in patients with penicillin allergy, and the addition of preoperative gram-negative coverage (e.g., gentamicin) is appropriate in such cases, given vancomycin's poor

*This chapter is a revision and update of that included in the previous edition of this book written by Robert G. Johnson.

FIGURE 155-1 ■ With respect to etiology, mediastinitis may be either primary, arising without prior intervention, or secondary, occurring post intervention. Clinically, the anatomic anterior and middle compartments can be considered together, as mediastinitis occurs most commonly in these combined spaces secondarily as a postoperative complication of cardiac operations. Esophageal pathology accounts for the overwhelming majority of mediastinal infections of the posterior compartment. (From Drake RL, Vogl AW, Mitchell AW: *Gray's Anatomy for Students*, 2/e. Philadelphia: Churchill Livingstone, 2009. Fig 3-5.)

coverage of such organisms.²⁰ Topical vancomycin has been shown to be effective in decreasing the incidence of sternal infections, and it is used routinely in some practices.²¹ Evidence-based guidelines from the Society of Thoracic Surgeons recommends gram-positive prophylaxis for no more than 48 hours, in addition to preoperative nasal mupirocin.^{17,20}

Diagnosis

Patients with mediastinitis after sternotomy generally have clinical signs of wound drainage and sternal instability, but neither may be present initially. Fever and leukocytosis are common. Some patients manifest signs of sepsis, with mental status changes and hemodynamic compromise. Mediastinitis can very rarely appear as early as 1 day after operation or as remotely as months after an operation.

Rarely, those patients who have an indolent course presenting many months after operation may have isolated deep involvement, tracking down to the aorta and/or involving some artificial material such as a plectet or a braided suture.

The variable diagnostic accuracy of imaging techniques for the diagnosis of mediastinitis permits them to be supportive²² but rarely, if ever, definitive. This is especially true during the early time frame (<30 days), when the vast majority of patients present. During this time, fluid collections and mediastinal soft-tissue changes are common, if not universal, with both being nonspecific for infection.²³

Technetium-99m leukocyte imaging can identify patients who have DSWI and require aggressive surgical débridement.²⁴ In one study, the patterns of intense uptake at 4 and 20 hours or increasing uptake between 4 and 20 hours were 100% sensitive and 89% specific for the detection of DSWI. The scan is useful in patients with suspected DSWI when clinical examination fails to confirm a diagnosis or when deep sternal aspirates of the SWI are equivocal. Leukocyte imaging is not useful for detecting superficial SWIs.²⁵

A profile of abnormal cytokine levels has been characterized,²⁶ with the terminal SC5b-9 complement complex concentration being substantially higher in patients with mediastinitis and having no overlap with the values in nonmediastinitis, post-cardiac surgery controls. In difficult-to-diagnose cases, blind retrosternal, subxiphoid needle aspiration and culture have been variably employed, and aspiration with ultrasound guidance has been reported after cardiac transplantation.²⁷ A recent small series suggested diagnostic success in patients without classic signs of infection by anteriorly inserting a 22-gauge needle percutaneously and aspirating between the recently closed sternal edges. Cultures and Gram stains were used to establish the presence of infection, with a high degree of specificity and sensitivity.²⁸

Treatment

The different technical approaches to treat anterior mediastinitis are related to the interval since the antecedent operation, the depth extent of the infection, and the acuity of the patient.²⁹

The classification by Pairolero and Arnold,³⁰ which is based on clinical rather than microbiologic features, can be used to practically approach the different types of clinical entities. There are three major types of sternomediastinitis in this system.

Type I sternomediastinitis manifests with serosanguineous drainage within a few days after sternotomy. Pus, osteomyelitis, and chondritis are notably absent. Mediastinal tissues are still soft and pliable. Bacterial cultures are initially negative or yield staphylococci. In such cases, the sternotomy is reopened, all blind pockets are eliminated, and the mediastinum is irrigated. This type of infection is best managed by the reinsertion of drainage tubes and reclosure of the sternum with either a variation of the Robicsek³¹ weave or a commercially available plate fixation device. Aggressive intravenous and topical antibiotic treatment should be used in these cases.

Type II sternomediastinitis is a fulminant process that occurs 1 to 3 weeks after surgery. In addition to reopening, drainage, and irrigation, these patients also require débridement of the necrotic soft tissue, bone, and cartilage. This may be performed initially, when the wound is reopened but may be delayed if the patient is septic or if his or her general condition is too critical to allow a major intervention. An effort should be made to remove all foreign materials such as felt pledgets and pacing wires. Exposed suture lines can be reinforced with autologous tissue, such as fascia lata, or covered with muscle flaps. The wound is then kept open and treated with daily dressing.

Type III sternomediastinitis occurs 1 month to 1 year after surgery. The patient typically presents with chronic draining sinus tracts that lead to the infected sternum, cartilages, or retained foreign bodies. Repair requires wide exposure, extensive débridement, often total sternectomy, and flap coverage using autologous tissues.

Diluted antibiotic, povidone iodine, and aqueous acid solutions have been reported as irrigation protocols.^{29,32} The duration of irrigation has varied from 3 days to 1 week, while systemic antibiotics are continued, as would be the case for other adult bone infections.³³

The cultures obtained at operation dictate the systemic antibiotics that will ultimately be used, but initial coverage may include a second-generation cephalosporin and gram-negative coverage until a Gram stain or the culture results are definitive.

If a two-stage approach is indicated, the approach involves an interval during which the sternum and skin are left open and a wound vacuum device placed.^{34,35} Open management of sternal wounds is associated with a risk of sudden cardiac hemorrhage from the exposed grafts, the aorta, or (most frequently) the right ventricle. The risk of death in such patients is very high (>50%).³⁶⁻³⁸ Given these risks, it has been recommended that close attention be paid to the proximity of the sternal edges and the right ventricle or grafts. Decreased abrasive contact may be afforded by the use of sedation, possible muscle paralysis, and mechanical ventilation until coverage can be achieved.

Whether used as an initial single-stage procedure or as a secondary procedure, tissue transposition into the anterior mediastinum has

dramatically changed the prognosis of this once often fatal complication.³⁹ Well-vascularized omentum or a variety of muscle flaps can be used.

The sternum may be left open with the tissue flap between the remnant edges, or rarely, it may be closed over the flap. Either way, closed suction drains are required for the large, mobilized skin flaps and sometimes beneath the transposed tissue flap.

The use of omentum versus any specific muscle flap may be dictated by availability (e.g., in patients with prior laparotomies), but when the option exists, the use of omentum has been touted as advantageous over muscle flaps,⁴⁰ although it has also been associated with poorer survival,⁴¹ perhaps related to patient selection. Omentum has also been successfully employed in infections after ascending aortic replacement for its properties of improving oxygen supply, enhancing antibiotic delivery, and enhancing the immunologic response while absorbing secretions that can lead to bacterial proliferation.⁴² Skin coverage over a transposed flap may be accomplished by primary presternal skin reapproximation or split-thickness skin grafting, or, with the rectus muscle, a skin paddle may be transposed as well.

As noted earlier, debrided sternal wounds may be prepared for flap coverage by the use of a closed high-pressure vacuum system in which a polyurethane foam (400- to 600- μ m pore size) is cut to fit the anterior mediastinal space and sealed to the skin, permitting a vacuum (-50 mm Hg) to be generated over the entire wound surface. The device is changed regularly to avoid tissue ingrowth, and whenever the anterior surface of the heart is in contact with the foam, it should be changed at least every 72 hours to avoid adhesions, which could have catastrophic consequences. Particularly with smaller wounds, the vacuum treatment may obviate the use of a flap coverage, as the wound heals secondarily, with obliteration of the space over a period of weeks.^{43,44}

Prognosis

Although the mortality of mediastinitis has improved dramatically over the past 2.5 decades, the likelihood of death remains high, as reported in a larger series (12.8% to 47%), more often from associated comorbidities or complications such as an additional infection.⁴⁵ Early detection with expeditious operative débridement and tissue coverage are the major advances that have allowed this improvement to take place. Importantly, it is not merely acute mortality that is elevated in patients with post-cardiac surgery mediastinitis. In studies from the Northern New England Cardiovascular Disease Study Group, with adjustment for various comorbidities, the 4-year mortality for patients with a postoperative deep sternal infection was three times greater than that for patients without this complication, and this increased all-cause mortality rate persisted with up to 10 years of follow-up. For patients surviving for longer than 6 months after a cardiac operation, the incidence of death was 70% higher than the rate among patients who did not have a mediastinal infection.⁴⁶

POSTERIOR MEDIASTITIS

Acute infections that arise in the posterior mediastinum generally result from disease that may be primary to the esophagus or, more commonly in the United States, secondary to esophageal intervention.⁴⁷

Primarily, esophagitis (e.g., in immunocompromised patients with fungal or viral organisms) may extend through the esophagus, resulting in mediastinitis. Abscess formation, presumably secondary to hematogenous spread, can occur.⁴⁸ Esophageal perforation (often at the gastric junction) from a swallowed foreign body has also been reported.⁴⁹

Esophageal operations may be the source of an infection due to anastomotic disruption, but as transhiatal esophagectomy is increasingly employed for patients with esophageal cancer, its cervical gastropharyngeal anastomosis mostly avoids the consequences of mediastinitis. Still, among patients with an intrathoracic esophagogastric

anastomosis, a leak may occur in 4.3% to 8.7% of patients.⁵⁰ Traumatic injuries to the trachea, proximal bronchi, or esophagus obviously may also result in the contamination of this space. Other causes of posterior compartment mediastinitis include the classic Boerhaave's syndrome characterized by the rupture of the lower esophagus post retching and, more rarely, the erosion of a broncholith from a partially or completely obstructed bronchus.⁵¹

Diagnosis

Given a relevant history, the presence of cervical pain and/or chest pain with a high fever would strongly suggest the diagnosis. Supraclavicular crepitus may be identified in patients with upper mediastinal pathology but is generally absent initially in those with middle or lower esophageal disease. Leukocytosis may be the singular early laboratory abnormality. Furthermore, sepsis with mental status changes and hypotension may occur. Certainly, in some of these patients, plain chest film may reveal a pleural effusion, and more rarely, air may be seen in the retropharyngeal space or other abnormal locations along the length of the mediastinum posterior to the pericardium. Computed tomography (CT) scan with oral Gastrografin is the mainstay for diagnosis and localization, as it can clearly demonstrate any abnormal air or fluid collections along the esophagus or esophagogastric junction, and water-soluble contrast may diagnose the presence of an esophageal leak. If there is any concern for possible aspiration, angiographic contrast agents are favored instead of Gastrografin, as the latter can cause more severe pneumonitis if aspirated, and barium will persist after the swallow, complicating the imaging of the future leak test. Transesophageal ultrasonography and fine-needle aspiration have been jointly used to diagnose a variety of periesophageal infections,⁵² and this bedside technique in critically ill patients likely has improved diagnostic accuracy over standard CT imaging.

Treatment

A contained esophageal disruption (extravasation of contrast that drains rather promptly back into the lumen) may be managed successfully in stable patients by serial clinical evaluation, limited oral intake, antibiotic therapy, and repeat imaging.⁵³ This may be particularly true in young children.⁵⁴

In patients with more frank mediastinal contamination not confined to the local perforation but identified within the first 24 hours, operation with primary repair and drainage is most often indicated.^{55,56} If the length of time since the perforation is sufficiently short and the injury is sufficiently small, so that local inflammation is limited, primary repair of a disruption—preferably with viable vascularized tissue buttressing—has been successfully employed,⁵⁶ even after 24 hours.⁵⁷ Success has also been recently reported with the use of covered self-expanding esophageal stents.⁵⁸ Image-guided nonoperative drainage with antibiotics has been successfully employed in selected cases where a defined collection or abscess could be identified.

In a case series reported by Ben-David et al., uncontained acute (less than 24 hours) esophageal perforations in the chest greater than 2 cm in size were successfully treated with a combination of endoscopically placed stent, minimally invasive laparoscopic/thoroscopic mediastinal drainage, and a laparoscopically placed gastrostomy or jejunostomy tube. By adopting this treatment algorithm, esophageal leak occlusion was confirmed in all patients within 24 hours of the esophageal stent placement, and 73% of the patients were able to begin a diet 48 hours after their esophagogram confirmed no further extravasation of contrast.^{59,60}

In patients with more extensive local inflammation, such as those diagnosed more than 24 hours after perforation and those who are more systemically ill, drainage with or without some esophageal diversion may be employed.

Continued sepsis and multiple organ failure are the most common causes of death among these patients, and multiple operations to excise

necrotic tissue and drain the space are sometimes required before definitive reconstruction.

MIGRATORY AND CHRONIC MEDIASTINAL INFLAMMATION

The mediastinum may be infected secondarily from contiguous acute infections involving adjacent anatomic spaces such as the pleurae, lungs, spine, intraabdominal processes, and retroperitoneum.⁶¹

Perhaps the most dramatic and well described of the migratory mediastinal infections are those that descend from the neck, which is known as *descending necrotizing mediastinitis*. These include those infections that arise as classic Ludwig's angina (odontogenic or non-odontogenic) or from cervical puncture wounds. Gravity and the negative pressure of the thoracic cavity have been cited as reasons for this descent through the pretracheal space into the upper posterior mediastinum. These patients are often young and may have a history of a dental infection. Cervical pain, cellulitis, necrosis, and abscess formation may occur, and a high index of suspicion leading to CT imaging can be diagnostic. Broad-spectrum antibiotics are essential and must be accompanied by cervical and mediastinal drainage directed by the clinical and radiologic findings.^{62,63} Drainage may be accomplished in a variety of ways including right thoracotomy, left-sided video-assisted

thoracoscopy, or an anterior clamshell incision. The mortality of this condition has historically ranged from 20% to 40% and increases directly with the interval between the onset of symptoms and diagnosis.

Oropharyngeal cervical infections descending into the mediastinum have been successfully managed with antibiotics and a combination of percutaneous drains and/or videoscopic débridement.^{61,64} In any case, aggressive imaging surveillance and a commitment to achieving and maintaining adequate drainage (multiple varied procedures) are necessary to successfully manage this relatively rare life-threatening disorder.⁶⁵

Mediastinal fibrosis is a chronic condition that may present precipitously when the process constricts a mediastinal structure, compromising its lumen. Pulmonary vein, pulmonary artery,⁶⁶ vena cava,⁶⁷ and tracheal stenoses are the most commonly seen. The diagnosis is generally established by CT or magnetic resonance imaging, which reveals a diffusely infiltrating, and sometimes calcified, mass. Bronchoscopy may contribute to the diagnosis.⁶⁸ The fibrosis is a benign, acellular proliferation of fibrous collagenous tissue that is idiopathic or may be an immunologic sequela of an intervention (e.g., radiofrequency ablation) or infection (mycotic, specifically, and most commonly, *Histoplasma*).^{69,70} Treatment may include steroid therapy⁷¹ and local dilation of the stenotic lumina with stents or operation.⁷²

Epistaxis is an acute hemorrhage from within the nasal cavity including the nasopharynx and accounts for 0.5% of all U.S. emergency department visits. Approximately 60% of individuals experience epistaxis at least once in their lifetime, although only 6% of cases require medical treatment.^{1,2} The peak incidence of epistaxis in adults is in the 45-65-year-old age group, and the incidence of severe posterior bleeding is greater.³ Special aspects regarding the care of critically ill patients with epistaxis including prevention, diagnosis, and management options will be discussed in this chapter.

ANATOMY

The vascular supply of the nasal cavity forms from the terminal branches of the internal and external carotid arteries. The majority of epistaxis (90%-95%) occurs on the anterior nasal septum at a region called *Little's area*. This area is supplied by Kiesselbach's plexus, a network of vessels from three large thin-walled arteries (sphenopalatine artery, anterior ethmoidal artery, and superior labial artery).⁴ Epistaxis is classified as anterior or posterior, although no clear landmarks separate the two.^{1,5} Melia and McGarry proposed that anterior bleeding is from a source anterior to the plane of the pyriform aperture (the anterior bony nasal aperture), which includes bleeding from the anterior septum and from the vestibular skin and mucocutaneous junction. Posterior bleeding is from a vessel situated posterior to the pyriform aperture and allows for further division into the lateral wall, septal, and nasal floor bleeding.⁶ The two primary sites of posterior epistaxis include the posterior lateral nasal wall and the posterior nasal septum, with the most common artery involved being the sphenopalatine artery. Epistaxis from the anterior ethmoidal artery is less common and is typically associated with midface trauma or iatrogenic injury during endoscopic sinus surgery.^{7,8}

DIAGNOSIS

It is important that the clinician wear appropriate safety clothing and equipment (disposable apron, gloves, surgical face mask, suction, and headlight). It is also important to gather details of the initial presentation, previous bleeding episodes, comorbid conditions, and current medications. Coagulation screening is only indicated when the clinical history suggests coagulopathy of a known use of anticoagulants.⁹ Warfarin is a commonly prescribed anticoagulant, and patients with epistaxis on warfarin are older, have longer mean hospital stays, and show trends that they require more aggressive treatment to control. In a review of patients taking warfarin with epistaxis, it was found that more than 75% of the patients were over-anticoagulated at the time of admission.¹⁰ Critically ill patients are frequently supine, with decreased alertness, and blood may drain into the nasopharynx and, subsequently, the stomach, making it difficult to differentiate from gastrointestinal bleeding. An anterior speculum exam with a good light source usually allows the identification of focal anterior bleeding. Generalized mucosal ooze in a patient with systemic coagulopathy and large amounts of bleeding that obscures visualization can make identification of the source difficult. In addition to the anterior/posterior classification system discussed above, bleeding can be classified as venous/

arterial or high/low flow based on the rate of bleeding. Venous bleeding can involve low flow, such as mucosal oozing, or it can be high flow from structures such as the cavernous sinus. Arterial bleeding can be low flow from oozing from small perforating vessels, or it can be high flow in carotid artery injuries.¹¹ Epistaxis can also be classified as primary or secondary when there is an underlying coagulopathy associated with anticoagulant/antiplatelet medications.⁶ For patients in which anterior bleeding is not easily identifiable, nasal endoscopy has been shown to identify over 80% of bleeding sites not otherwise seen and reduce the duration of hospital admission. Chiu and McGarry reported positive identification of 94% of posterior bleeding sites in 50 consecutive patients, while Supriya et al. identified 38 of 47 posterior bleeding sites in a series of 100 patients, with an overall positive identification rate of 91%.^{8,12}

TREATMENT

General management includes the protection of the airway, addressing hemodynamic compromise, and controlling active hemorrhage. Patients with a reduced level of consciousness or head injury are at risk of aspiration and should require consideration of airway protection with endotracheal intubation. Intravenous access and fluid resuscitation should be addressed quickly, as patients can become unstable. The first priority is to control or slow the active hemorrhage with some form of temporizing packing. Commercially available anterior or posterior balloon combination packs can be used with the goal of slowing the rate of blood loss while the setup of anticipated equipment is established. Prior to insertion of these packing materials, an attempt can be made by simply applying pressure to the nose, while the patient is positioned upright and leaning forward for 20 minutes. The goal here is to slow the blood loss rate by collapsing the bleeding vessels and forming a clot.

Treatment—Anterior Bleeding

Cautery of an identified bleeding point is the optimal method of management in adult epistaxis and can successfully control anterior bleeding, with silver nitrate and electrocautery as options. Silver nitrate is applied by rolling the applicator stick between your thumb and first finger while gently applying the tip to the area you wish to cauterize for about 5 to 10 seconds. Care should be taken not to burn the nasal skin as you enter the nose or aggressively use it on the septum. Start adjacent to the vessel, making an orbit around the vessel before rolling the tip in to the center, as re-bleeding is common when going straight for the site. Shargorodsky et al. found that cautery had a significantly lower treatment failure rate (defined as a re-bleed requiring intervention by a physician within 7 days) and a lower mean number of interventions required to achieve lasting hemostasis with nondissolvable packing. Among the patients who required admission, those who underwent directed vascular control had fewer inpatient days.¹³ If cautery does not control the bleeding, a nasal pack will be required. Nasal packs should be introduced into the nose directly front-to-back following the floor of the nose. Never place it upward, as this does not work, is painful, and increases the risk of complications. Commercially

available packs are available and consist of balloon/hydrocolloid fabrics that expand after placement into the nasopharynx. Most of these have a string or tubing that should be taped to the patient's cheek to secure it.

Treatment—Posterior Bleeding

Severe idiopathic nontraumatic posterior bleeding typically occurs in the elderly, who often have underlying cardiac and respiratory comorbidities. It should be suspected after appropriate anterior control measures have been taken and bleeding continues. Typically, a 12 French Foley catheter or similar item is used in conjunction with a ½-inch ribbon gauze or commercially available anterior packing supplies. The catheter balloon should be tested with saline prior to use. A nasal decongestant and topical local anesthetic solution should be administered to the nasal cavity and on the ribbon gauze. The catheter is lubricated and advanced into the nose until the tip can just be seen passing the soft palate in the mouth. At this point, the catheter needs to be pulled back 1 cm as the balloon inflates in the nasopharynx. Between 5 to 10 mL of saline is used to inflate the balloon, and once inflated, the catheter is pulled taut so that the balloon is effectively occluding the posterior nasopharynx at the back of the nasal cavity. Anterior packing is then performed by folding layers of the ribbon. These patients are at risk for adverse events such as re-bleeding and hypoxia, likely due to comorbidities such as cardiovascular disease, pulmonary disease, renal disease, obesity, and obstructive sleep apnea.^{14,15} For continued bleeding, surgery or embolization is an option. Moshaver et al. showed that compared with surgical intervention, posterior nasal packing resulted in a significantly shorter mean hospital stay and reduced health care costs. The overall success rate was 89%, and no difference was found in the complication rates between the two treatment options.¹⁶ Arterial embolization appears similar to surgery in terms of its success in controlling intractable epistaxis, with several recent studies showing success rates of 80% to 90%.¹⁷⁻²¹ The advantage of surgery is a lower risk for major complications such as stroke, blindness, and soft tissue ischemia. The advantage of embolization is the ability to perform the procedure under local anesthesia, thus avoiding general anesthesia in patients with comorbidities, as well as the improved diagnosis of vascular abnormalities such as malformations and pseudoaneurysms.

Treatment—After Packing the Nose

The packing is usually kept in for 5 days, but this is usually physician and institution dependent. Patients do not tolerate nasal packing well. Shargorodsky et al. examined whether the duration of packing was associated with the recurrence of epistaxis following removal and did not demonstrate a significant difference between the recurrence rate and the number of pack days, showing no evidence that removing the packing after fewer than 5 days was associated with increased recurrence of epistaxis.¹³ Furthermore, good results have been shown in packing durations of 1 to 3 days, with the control of bleeding as high as 85% for anterior epistaxis.²² Nasal packing of all types requires gram-positive coverage for prophylaxis against toxic shock syndrome. *Staphylococcus aureus* can be isolated from the nasal cavity in one-third of these patients, of whom 30% produce the exotoxin responsible for toxic shock syndrome.²³ Other complications include pressure necrosis of the palate, alar, or skin and displacement with airway obstruction.

MEDICOLEGAL THOUGHTS

The absence of a defined management algorithm, wide therapeutic options, and the potential for severe complications all contribute to epistaxis as a target for medicolegal cases. Understanding the variables will assist in advancing strategies and enhancing patient care. The most common reason has been due to the alleged failure of the treating physician to recognize complications in a timely manner and delays

in the subsequent diagnosis, such as cancer and retained foreign bodies.²⁴⁻²⁶ It is important to realize that epistaxis is a sign, not a diagnosis. Other cases have been related to the failure of recognition of anatomic variations, which led to blindness and stroke due to inadvertent embolization.^{5,27} This shows the importance of preinterventional imaging. Last, malposition or inadequate nasal packing with complications such as aspiration and dislodgment have been found throughout the hospital stay.²⁸

SPECIFIC INTENSIVE CARE UNIT SITUATIONS—NASAL INTUBATION

Nasotracheal intubation commonly causes epistaxis from injury to the nasal mucosa or turbinate. Good mucosal preparation for nasotracheal intubation should include adequate lubrication, topical local anesthetics, and vasoconstrictors. Moreover, if resistance is met, the tube should be slightly rotated to allow better passage or the other nare should be attempted.^{29,30} The inferior turbinate and the adjacent septum are the most common sites of nasal damage.^{31,32} Placement into intracranial compartments has occurred in the setting of skull base trauma. Blind placement in these situations may be associated with severe complications. Although posterior nasal packing should not be performed in the presence of nasal bone fractures, severe epistaxis may necessitate nasal packing with the use of balloon systems or arterial embolization ligation.^{33,34} Cribriform plate fractures are the most common site for intracranial catheter placement and can occur with even small amounts of pressure.

SPECIFIC INTENSIVE CARE UNIT SITUATIONS—POSTOPERATIVE EPISTAXIS

Sellar and parasellar lesions are typically approached through transphenoidal surgery, and postoperative bleeding originates from the external carotid system. Redundant mucosa, highly vascular and friable mucosa, large septal deviations, septal spurs, and complex sphenoid septations can make endoscopic transphenoidal surgery difficult and increase the risk for epistaxis.³⁵ Management of bleeding immediately postoperatively involves nasal packing and re-exploration in the operating room if the packing is not successful. In delayed bleeding, otorhinolaryngologic services typically perform endoscopic packing, balloon tamponade, silver nitrate application, and/or electrocautery. If these measures do not stop the bleeding, angiography followed by embolization can be performed.³⁶ Postoperative hypertension is generally viewed as a risk factor for epistaxis and is also an independent risk factor for persistent spontaneous epistaxis.³⁷

SPECIFIC INTENSIVE CARE UNIT SITUATIONS—MASSIVE FACIAL TRAUMA

Traumatic pseudoaneurysms of the internal carotid artery are rare but can be a fatal cause of epistaxis, with a mortality rate as high as 50%.^{38,39} Pseudoaneurysms or localized arterial disruptions are caused by blunt or penetrating trauma. Shearing forces and hemorrhages in the arterial wall weaken the artery and allow formation, and the continued pulsatile forces cause erosion on the thin bone layer.^{40,41} The Maurer's triad, which consists of unilateral blindness, orbital fracture, and massive epistaxis, is considered pathognomonic for internal carotid artery pseudoaneurysms.⁴² The diagnosis is often delayed because of a latency period between the trauma and the bleeding, which averages 3 weeks in 88% of cases.^{43,44} Angiographic imaging is the gold standard, with endovascular techniques being the preferred therapeutic approach.

NOVEL AND ADJUNCTIVE THERAPIES

Vasoconstrictors, hot water irrigation, and topical hemostatic compounds have all been used as adjunctive therapies to the abovementioned procedures for the control of bleeding. Hot water irrigation via a balloon placed in the nasopharynx for approximately 3 minutes at

50°C to induce mucosal edema (and occlude the bleeding vessel) has been shown to control posterior epistaxis.^{45,46} Topical hemostatic compounds are now available, consisting of gelatin granules and human thrombin. Studies show higher effectiveness, ease of application, and lower discomfort scores for their insertion and removal.⁴⁷

KEY POINTS

1. In the critically ill patient, diagnosis of epistaxis may be more difficult due to supine positioning and decreased alertness and is often confused with upper gastrointestinal bleeding.
2. Epistaxis is a sign and not a diagnosis; once bleeding is controlled, the search for the etiology should be conducted. Coagulation studies should be performed in those on anticoagulant/antiplatelet medications, with consideration of correction.
3. For intractable epistaxis, options should include surgery or embolization. Surgery has the advantages of decreased complication rates of stroke and blindness, while embolization has the advantage of avoiding general anesthesia in patients with nasopharyngeal bleeding.
4. Aspiration, hypoxia, and dislodgment complications with nasal packing must be continuously evaluated for, especially in patients with severe comorbidities.

The initial days of care for a cardiac surgery patient present multiple challenges for an intensivist. The intensive care unit (ICU) stay for most patients lasts for 24 to 48 hours, but during this critical period, life-threatening problems such as low cardiac output (CO), arrhythmias, and coagulopathy may occur. After 48 hours, the problems encountered tend to become more like those experienced by other groups of critically ill patients.

CARDIAC SURGERY PATIENT IN THE INTENSIVE CARE UNIT

History of Cardiac Surgery Linked to the History of Intensive Care

The development of modern cardiac surgery is intimately related to the development of the ICU. Until the 1950s, cardiac surgery was limited to the control of traumatic injuries and the closed repair of valves. The development of the extracorporeal pump oxygenator in 1953 ushered in the era of open-heart surgery.¹ Heart valve replacement then became possible, and subsequently in the 1960s, coronary artery bypass grafting (CABG) for ischemic heart disease was developed and rapidly popularized.²

Several studies have demonstrated that risk-adjusted mortality rates after CABG vary significantly among surgeons and hospitals and that mortality is related both to the number of surgeries performed by each surgeon and the total volume of procedures performed at the hospital.³⁻⁶ For high-risk surgical patients, survival is also related to the characteristics of the ICU care.⁷

Changing Epidemiology of Cardiac Surgery

Over the past decade, the population of patients treated with cardiac surgery has changed dramatically. Advances in cardiology including reperfusion therapy, angioplasty, stenting, and drug-eluting stents have obviated the need for surgical approaches to treatment except for particularly complex problems or after failure of other less invasive modalities. In the year 2000, 561,000 patients in the United States underwent percutaneous transluminal coronary angioplasty (PTCA), an increase of 262% relative to 1987. In the same year, 314,000 patients underwent CABG. Multiyear trends, represented in Figure 157-1, show a leveling off and subsequent decrease in the overall number of patients undergoing CABG.⁸ Studies comparing the use of stents versus CABG for left main disease have found no significant difference in rates of death, Q-wave infarction, or stroke; however, stenting was associated with higher rates of target vessel revascularization than was CABG.⁹

Even as younger patients are being treated with interventional techniques, the elderly are increasingly referred for operation. Although these operations are successful even in most octogenarians, they are associated with increased hospital mortality and longer ICU and hospital stays. It is clear, however, that good results in terms of long-term survival and quality of life are achievable.

Alternative Techniques for Cardiac Surgery

The increasing age of patients undergoing cardiac surgery and the relatively high incidence of adverse effects related to cardiopulmonary bypass (CPB) have led to the development of less invasive cardiac surgical techniques. These techniques are intended to decrease postoperative morbidity, reduce length of hospital stay, reduce costs, and hasten recovery of lifestyle (Table 157-1). Three major techniques have been proposed.

Minimally invasive direct coronary artery bypass (MIDCAB) differs from conventional CABG mainly in the type of surgical incision. Instead of median sternotomy, access is obtained via a left or right thoracotomy, a parasternal incision, or a partial sternotomy. Although the proposed benefit of such an approach is the reduction in morbidity related to median sternotomy, this advantage has not been demonstrated. MIDCAB grafting is a challenging technique and should be performed only in selected patients with favorable coronary anatomy. Both bare-metal and drug-eluting stenting have been shown to be inferior to MIDCAB for proximal left anterior descending coronary artery lesions, owing to higher reintervention rates and similar results in mortality and morbidity.^{4,10}

Off-pump coronary artery bypass (OPCAB) is performed on a beating heart without the benefit of CPB. The proposed advantage of this procedure is reduction of morbidity related to hypothermia and CPB. The procedure is undertaken using partial to full heparinization. Extubation may be achieved earlier in these patients because they do not require rewarming and are less coagulopathic. A subset of patients cannot tolerate the extent of retraction of the heart required for the surgery and need to be urgently placed on CPB. These patients may suffer ischemic myocardial injury and require support with inotropes or intraaortic balloon pumping (IABP) during the postoperative period.

A third method of minimally invasive cardiac surgery is the port-access technique. This operation entails obtaining access for CPB with the use of endovascular catheters. It allows surgery to be performed using CPB via either a left or a right thoracotomy. The technique is particularly useful for mitral valve replacement through a right thoracotomy and for redo CABG (avoiding the complications associated with repeat sternotomy). The port-access technique has been shown to be safe and is associated with shorter lengths of stay, reduced transfusion requirements, fewer infections, decreased incidence of renal failure, and less atrial fibrillation (AFib) compared with conventional techniques.¹¹ Widespread adoption of this technique has been limited by the technical complexity of placing the required catheters, which requires both extra time and a specially trained, skilled operative team. As the techniques of minimally invasive cardiac surgery continue to evolve, the intensivist caring for cardiac surgical patients must continue to keep abreast of these new methods.

Organization of the Postoperative Cardiac Surgery Unit

Optimal results from cardiac surgery require a skilled, dedicated, and multidisciplinary ICU team. Patients undergoing cardiac surgery are

usually admitted to the hospital on the day of surgery and arrive in the ICU directly from the operating room (OR). A typical patient is transferred to a step-down unit on the morning after surgery. This unit allows continued monitoring with telemetry for an additional 24 to 48 hours. Patients remaining in the ICU beyond 48 hours tend to become similar to a standard ICU population, as they develop secondary complications such as sepsis, pneumonia, and acute respiratory distress syndrome (ARDS).

Guidelines developed by the American Heart Association and the American College of Cardiology outline the requirements for cardiac surgical ICUs.¹²⁻¹⁴ These include the development of protocol-driven care, a minimum number of cardiac surgical ICU beds that is half the number of surgeries performed per week, and one-to-one nursing care during the first night in the unit. The ICU coverage by a dedicated intensivist has been shown to improve outcomes in other types of

major surgeries and should be recommended after cardiac surgery as well.⁷

SEPARATION FROM CARDIOPULMONARY BYPASS AND THE END OF SURGERY

Successful management of a postoperative cardiac surgery patient begins by understanding what occurs in the OR because operative problems often persist after transfer to the ICU. An understanding of the technical and pathophysiologic aspects of CPB may help an intensivist to better manage the postoperative cardiac surgical patient.

Cardiopulmonary Bypass

The goal of CPB is to separate the heart and lungs from the systemic circulation so that the heart may be arrested while the surgical repair is performed. Blood is drained from the right side of the heart via a cannula in the right atrium or via the femoral vein advanced into the right atrium. The blood is collected in a reservoir and then pumped through an oxygenator that contains a membrane where the blood is oxygenated and carbon dioxide is removed (Fig. 157-2). A perfusionist controls both the fraction of inspired oxygen and the rate of oxygen flow through the circuit, thereby controlling the patient's arterial oxygen and carbon dioxide levels, respectively. The treated blood then passes through an air filter and is returned to the patient via an arterial cannula placed in either the ascending aorta or the femoral artery. The perfusionist controls the amount of systemic flow provided to the patient (i.e., CO). Mild to moderate systemic hypothermia (28°C–34°C) is used during bypass to minimize oxygen consumption by both the body and the brain. After adequate CPB is established, an aortic cross-clamp is applied to the ascending aorta, between the aortic cannula and the heart. The interval when the cross-clamp is applied is

FIGURE 157-1 ■ Trends in cardiovascular operations and procedures in the United States, 1979–2000. PTCA, percutaneous transluminal coronary angioplasty. (From American Heart Association. Heart disease and stroke statistics—2003 update. Dallas, TX: AHA; 2003.)

TABLE 157-1 Comparison of Minimally Invasive Cardiac Surgery Techniques

| TECHNIQUE | INCISION SITE | CANNULATION SITE | ADVANTAGES | DISADVANTAGES |
|-------------------|---|---|---|---|
| Conventional CABG | Median sternotomy | Ascending aorta | Excellent exposure | Mediastinitis |
| | | Right atrium | Stable closure Extensive experience | Slow recovery of upper extremity function Postoperative cough limited by pain |
| MIDCAB | Left thoracotomy, or Paramedian or right thoracotomy, or Partial sternotomy | Ascending aorta Right atrium | Avoids median sternotomy Useful for redo procedure Hastens recovery of upper extremity function* | Limited exposure No cost savings May require multiple incisions |
| Port-access | Right anterior thoracotomy, or Paramedian or left thoracotomy | Ascending aorta via right paramedian port Femoral vein | Avoids median sternotomy Avoids atriotomy Access to mitral valve Smaller skin incision Decreases hospital stay* Decreases atrial fibrillation incidence* Decreases transfusion* Decreases rehabilitation time* | Increased cost of equipment Contraindicated in patients with ascending aortic pathology Limited operative exposure Significant learning curve unlikely to decrease cerebral emboli |
| OPCAB | Median sternotomy, or Right or left thoracotomy, or Partial sternotomy | None | Avoids aortic manipulation Avoids atriotomy and CPB Normothermia Decreases atrial fibrillation incidence* Decreases transfusion* Decreases neurologic morbidity† Decreases pulmonary morbidity† | Cost of equipment Slow recovery of upper extremity function Mediastinitis Increases intraoperative ischemia Undetermined graft longevity |

*Limited supporting evidence exists.

†Proposed benefit.

CABG, coronary artery bypass grafting; CPB, cardiopulmonary bypass; MIDCAB, minimally invasive direct coronary artery bypass; OPCAB, off-pump coronary artery bypass.

referred to as *ischemic* time, because no blood is circulated through the heart during this period. The heart is arrested by infusing a high-concentration potassium solution into the native coronary arteries (antegrade cardioplegia) via a cannula placed between the aortic cross-clamp and the heart. Cardioplegia may also be given “backward,” through the venous system of the myocardium (retrograde cardioplegia) via a catheter placed in the coronary sinus. Potassium is used as the arresting agent because it stops the heart from beating and minimizes myocardial oxygen consumption.

Myocardial Protection

Several measures are taken to protect the heart during ischemic time, because irreversible myocardial damage may otherwise occur. Electromechanical arrest is the most important protective measure, because the beating action of the heart accounts for about 85% of the heart's total oxygen consumption. The heart is usually cooled to about 10°C with a cold cardioplegia solution (4°C) supplemented with topical ice slush. Additionally, the left ventricle is “vented” to prevent distention, which could lead to subendocardial ischemia. Finally, various additives are included in the cardioplegia solution to minimize myocardial edema, maintain normal intramyocardial pH, and provide substrates for anaerobic metabolism. The adequacy of intraoperative myocardial protection is critical for determining the subsequent course and final outcome for a patient.

Separation from Cardiopulmonary Bypass

Weaning from CPB is the process whereby cardiopulmonary function is transferred from the bypass system back to the patient's own heart and lungs. Successful separation from CPB requires that the metabolic, cardiac, and respiratory parameters are as close to normal as possible.

Separation from CPB implies that the native circulation will be required to support the body's metabolic demands. The surgical team manipulates the heart rate and rhythm, preload, afterload, and myocardial contractility to achieve this goal.

In most cases, normal sinus rhythm is restored after discontinuation of cardioplegia and rewarming of the heart. Occasionally, discontinuation of cardioplegia and rewarming lead to the onset of ventricular fibrillation; in such cases, electrical defibrillation is required. Other dysrhythmias commonly encountered are atrioventricular dissociation and atrial fibrillation (AFib). An attempt should be made to convert these to sinus rhythm by pharmacologic means. Bradyarrhythmias are treated by pacing, using temporary epicardial wires placed by the surgeon after completion of the repair. A heart rate of 70 to 90 beats/min usually is optimal. Pharmacologic support of the circulation may be needed to provide appropriate afterload or systemic vascular resistance (SVR) during separation from CPB. Most patients are vasodilated to some extent, possibly as a result of a systemic inflammatory response to CPB or the effects of rewarming, or both. As a consequence, the infusion of a vasoconstrictor is often required. Care must be taken to strike a proper balance so that increased SVR maintains adequate arterial blood pressure without excessively increasing left ventricular afterload and compromising CO.

Most often, myocardial function is adequate, and the infusion of an inotrope is not necessary. However, inotropic support is often needed for patients with a poor preoperative ventricular function or inadequate myocardial protection or revascularization during CPB. The optimal inotrope in this situation is a matter of considerable debate, and data are lacking to support a strong recommendation for a specific agent. Epinephrine, norepinephrine, dopamine, dobutamine, amrinone, and milrinone have all been used successfully. Intraoperative monitoring using transesophageal echocardiography (TEE) is particularly useful for titration of inotropic therapy.

Once all preparations for separation from CPB have been made, the perfusionist begins to wean the patient from bypass. This is done by slowly decreasing the amount of blood drained from the right atrium while simultaneously reducing flow into the aorta. Once the patient is off CPB (i.e., no blood is being drained from the right atrium into the circuit), the perfusionist, at the direction of the anesthesiologist or surgeon, may continue to infuse through the aortic cannula. This maneuver allows optimization of ventricular filling or preload. However, care must be taken not to overdistend the heart; also, during this period, TEE is extremely useful.

Reversal of Anticoagulation

After weaning from CPB, protamine is given to neutralize any residual heparin. Dosing may be based on the patient's weight, the total amount of heparin given, or an assay of residual heparin activity. Institutional preference governs the technique employed, but all have been proven effective. Several adverse responses to protamine administration are possible, including histamine-induced systemic hypotension, immunoglobulin E-mediated allergic reactions, and complement-mediated catastrophic pulmonary hypertension.

Transport and Admission to the Intensive Care Unit

After chest closure, confirmation of hemodynamic stability, and adequate medical and surgical hemostasis, the patient is transferred to the ICU. Transport of a critically ill patient is a potentially dangerous process and requires extreme vigilance. Transport between the OR and the ICU should be done with the same degree of monitoring as would be available at either end. This usually includes continuous monitoring of arterial blood pressure, pulmonary artery pressure and/or central venous pressure (CVP), electrocardiogram (ECG), and pulse oximetry. The transport bed should be equipped with a full oxygen tank, a bag valve mask, intubation equipment, resuscitation drugs, and a defibrillator. Care must be taken to ensure that infusions of vasoactive drugs are not interrupted.

On arrival in the ICU, the intensivist-led team assumes patient care. A detailed sign-out from the operative team ensures continuity of care. The sign-out should include a detailed history including an assessment of preoperative cardiac functional status, a list of preoperative medications, and a detailed description of the surgery. Key facts are the type of repair performed, target vessels (if the patient has undergone CABG), duration of CPB and cross-clamping, difficulties encountered in separation from CPB, presence of abnormal bleeding, and postoperative assessment of cardiac function. All treatments administered in the OR should be detailed, in particular, fluids, blood products, and vasoactive drugs.

Once care has been handed over to the ICU team, a thorough examination of the patient should immediately follow. This examination should include verification of endotracheal tube placement, type and position of arterial or central venous lines, chest tube position and patency, and presence and location of any epicardial pacing wires.

MONITORING THE POSTOPERATIVE CARDIAC SURGERY PATIENT

Hemodynamic Monitoring

All patients admitted to the ICU after cardiac surgery will have their blood pressure continuously monitored using an intraarterial line, which is usually placed in either a radial or a femoral artery. Accuracy of the measurements depends on strict attention to calibration, leveling, and removal of air from the tubing. After CPB, femoral arterial pressure may more accurately reflect central aortic pressures,¹⁵ but this problem is usually resolved by the time the patient arrives in the ICU. If the radial artery is cannulated, the hand should be examined for signs of ischemia.¹⁶ Vascular complications of femoral arterial lines are

extremely rare, but femoral catheters may be associated with an increased incidence of infection.¹⁷

Central venous access is required in all patients for drug administration and hemodynamic monitoring. In low-risk patients, a CVP catheter may be all that is needed, particularly if echocardiography is available as a backup. Pulmonary artery catheters have the advantage of allowing measurement of pulmonary artery occlusion pressure (PAOP), thermodilution, and CO, as well as sampling of the mixed venous blood saturation (SvO₂). Use of the pulmonary artery catheter remains controversial. Improved outcome due to the use of a pulmonary artery catheter for monitoring of cardiac surgical patients has not been demonstrated.¹⁸ Some studies showed an increased risk of death or adverse outcome when treatment was guided by the use of a pulmonary artery catheter.^{19,20} However, many of these studies have been criticized on methodological grounds, and the use of a catheter in cardiac surgery remains widespread.²¹ Current guidelines recommend the use of a pulmonary artery catheter in high-risk patients undergoing surgery in an appropriate practice setting.²² Such a setting is the one in which the physician and nursing staff are familiar with the catheter and trained to properly interpret the information obtained. If echocardiography is readily available, it is possible to manage even high-risk patients using a CVP catheter.

Electrocardiography

On admission to the ICU, the patient is connected to a continuous ECG monitor, and a formal 12-lead ECG is obtained. The cardiogram is examined for rate, rhythm, QRS complex morphology, and signs of myocardial ischemia. For patients who are being paced postoperatively, the type of pacing and the degree of capture should be assessed.

Continuous ECG monitoring allows detection of arrhythmias. If an arrhythmia is detected, a 12-lead ECG should be obtained, and serum electrolyte concentrations should be measured. Treatment of arrhythmias should be carried out using established protocols.²³ If a malignant arrhythmia occurs, myocardial ischemia should be considered as a possible precipitating cause.

Monitoring of trends in ST-segment elevation or depression allows early detection of postoperative myocardial ischemia. Although transient ST-segment changes are relatively common and of unclear significance, persistent changes should be investigated by obtaining a 12-lead ECG and measuring circulating levels of creatine kinase myocardial band (CK-MB), troponin-T, or troponin-I.^{24,25} If ischemia is strongly suspected, then echocardiography followed by coronary angiography should be considered. Findings from these studies may indicate the need for further coronary revascularization.

Chest Radiography

The postoperative chest radiograph should be systematically evaluated. Proper placement of the endotracheal tube and any central lines inserted should be confirmed. If a pulmonary artery catheter is placed, the location of its tip should be noted and adjusted as needed. The lung fields should be examined for the presence of pneumothorax (PTX) or consolidation. Additional air may be noted as subcutaneous emphysema or pneumopericardium, although these findings are of little clinical significance. Further examination of the lung fields commonly shows small areas of atelectasis and pleural effusion. The cardiac silhouette is often enlarged after surgery as a result of myocardial edema and accumulation of fluid in the open pericardial sac. Increasing size of the cardiac silhouette or pleural effusions on serial chest radiographs may be evidence of ongoing mediastinal bleeding.

Echocardiography in the Intensive Care Unit

Echocardiography is an excellent tool for evaluating chamber size and function and the adequacy of valve repair or replacement. Indications include postoperative assessment of left ventricular function, assessment of unexplained sudden hemodynamic deterioration, evaluation

to rule out pericardial tamponade, and workup of new cardiac ischemia. Limitations to transthoracic echocardiography include inadequate windows early after operation due to air and edema in the soft tissues and wound dressings.

TEE is increasingly being used as a tool to facilitate decision making in managing critically ill patients, including cardiac surgical patients. In the cardiac surgical ICU, this modality may have a particularly high yield when used to establish the cause of postoperative hypotension.²⁶ In one large series, a new diagnosis was established or an important pathology was excluded in 45% of TEE examinations performed in the ICU. Pericardial tamponade was diagnosed in 34 cases (11%) and excluded in 36 cases (12%). Other diagnoses included severe left ventricular failure and presence of large pleural effusions. The results of TEE had an impact on therapy in 220 cases (73%) by leading to a change of pharmacologic treatment and/or fluid administration, reoperation, or a decision that reoperation was unnecessary.²⁷

CLINICAL MANIFESTATIONS OF THE POSTBYPASS PERIOD

The Normal Course

Patients are typically admitted to the ICU intubated and ventilated. Sedation with a short-acting agent, typically propofol, is continued until the patient is ready for extubation.^{28,29} Once hemodynamic stability is ascertained and chest tube drainage is judged to be under control, the patient is allowed to awaken. There is no need for prolonged weaning from mechanical ventilation. A short trial of spontaneous ventilation is sufficient to determine whether respiration will be adequate without mechanical support. The rapid shallow breathing index (RSBI) has been shown to be a sensitive way to assess the likelihood of successful extubation.³⁰ The RSBI is calculated by dividing the respiratory rate (in breaths/min) by the tidal volume (in liters). Values of RSBI lower than 105 predict successful extubation. Chest tubes are commonly removed on the first postoperative day. The pulmonary artery catheter, if present, is discontinued, and the patient may be transferred to a step-down unit.

Fast-tracking of cardiac surgical patients refers to a comprehensive program designed to reduce both length of stay and hospital costs.^{31,32} As a part of this program, multiple anesthetic techniques designed to allow earlier postoperative extubation have been proposed, studied, and shown to be safe. These techniques may allow extubation in the OR.³³ The key to proper use of this technique is patient selection. Patients with unstable angina or a high degree of congestive heart failure (CHF) are generally not appropriate candidates for fast-tracking. The fast-track group has been shown to have shorter extubation times, shorter ICU or postanesthesia care unit stays, and a lower incidence of low CO syndrome.²⁹

Low Cardiac Output

Low CO is the most common problem encountered in the postoperative cardiac surgical patient. A hallmark of low CO is low blood pressure. However, a patient may have a low CO with tissue hypoperfusion and still maintain what appears to be an adequate blood pressure. In the postoperative state, the physician must continuously examine and monitor the patient for signs of hypoperfusion. Physical signs of inadequate tissue perfusion include altered mental status; cool, pale, or even cyanotic extremities; diaphoresis; and low urine output. Global measures of hypoperfusion include increased base deficit, elevated blood lactate concentration, and decreased SvO_2 . Although the clinician must consider CO in terms of adequacy of perfusion, blood pressure per se is still important. Both the brain and kidneys depend on adequate blood pressure to maintain tissue perfusion. Additionally, coronary artery blood flow is dependent on the diastolic blood pressure.

When assessing a patient with hypotension or signs of hypoperfusion, it is useful to consider the problem in relation to the components of CO—namely, preload, contractility, afterload, and rate and rhythm.

Preload

Preload refers to the stretch of the left ventricle at the end of diastole and is determined by the extent of diastolic ventricular filling. Adequate filling is required to ensure ejection in the subsequent systole. The most common cause of inadequate preload in postoperative patients is hypovolemia. Intravascular volume status should be continually monitored by assessing changes over time with respect to physical examination, chest tube output, and filling pressures (CVP, PAOP, or pulmonary artery diastolic pressure). Because none of the clinically measured filling pressures correlates perfectly with actual ventricular preload (i.e., end-diastolic volume) and correlation is particularly poor when the heart is diseased, it is often useful to obtain a snapshot of ventricular filling using echocardiography. By this means, it is possible to assess the relationship between measured filling pressures and actual preload in a specific patient. Preoperative catheterization data may also be helpful for determining this relationship. Hypovolemia should be treated with fluid replacement. Crystalloids are generally used. Surprisingly, there is no generally accepted hemoglobin concentration or hematocrit that should be used as a trigger for ordering transfusion of packed red blood cells.³⁴ Red cell transfusion has been associated with early morbidity and long-term adverse sequelae.

In some cases, low preload is not caused by absolute hypovolemia but by relative or distributional hypovolemia. CPB and subsequent rewarming may lead to vasodilatation and a subsequent hypotension. Intravascular volume expansion may be required to maintain perfusion. An acceptable alternative is administration of a low dose of vasopressor such as phenylephrine or norepinephrine to maintain an adequate perfusion pressure. Vasopressin in doses between 0.01 and 0.1 units/min has been demonstrated to be effective in this situation.^{35,36} Vasodilatation is usually a transient problem that resolves during the first several hours after separation from CPB. Continued vasodilatation after this period should prompt a search for another cause, particularly infection.

Pump Failure

Either or both ventricles may fail postoperatively. Decreased myocardial contractility may be caused by impaired preoperative function, inadequate revascularization at surgery, post-CPB reperfusion injury, or perioperative myocardial ischemia or myocardial infarction (MI). The incidence of infarction is approximately 5% in a large series.³⁷ Preoperative myocardial function and the adequacy of revascularization at surgery should be clear from the history. Determination of circulating levels of CK-MB or troponin postoperatively may provide evidence of perioperative ischemia or infarction.^{24,25} Often, diminished contractility after operation is caused by inadequate myocardial protection during surgery. Decreased myocardial contractility secondary to inadequate myocardial protection usually resolves within the first 24 hours postoperatively.

Persistent new myocardial dysfunction associated with ECG changes and echocardiographic evidence of new wall-motion abnormalities should raise suspicion that the problem is an occluded graft and MI. Measurements of CK-MB in serum are of limited usefulness because levels of this enzyme are commonly elevated after surgery as a result of manipulation of the heart and incision of the atria. If CK-MB levels are very high (>80 mg/dL), then perioperative MI is likely.³⁸ Cardiac troponins are more specific for diagnosing perioperative infarction. A comparison of CK-MB, troponin-T, and troponin-I showed that a troponin-I level of greater than 5 μ g/L was the most accurate indicator of MI.³⁹ Elevated serum concentrations of troponin-I are associated with a cardiac cause of death and major postoperative complications.⁴⁰ In addition, troponin-T concentrations measured after surgery are an independent predictor of in-hospital death after cardiac surgery.²⁵ If ischemia or MI is diagnosed, the patient may be taken urgently for angiography or reexploration and revascularization.

Postoperative valvular insufficiency may occur not only in patients with preexisting valvular lesions but also as a result of injury during surgery. The mitral valve is most commonly affected. Ischemia of the

papillary muscles due to inadequate myocardial protection or perioperative MI may lead to acute mitral regurgitation in the postoperative period. Diagnosis is often made by TEE in the OR, but inadequate CO and a new systolic murmur should prompt echocardiographic evaluation.

Rate and Rhythm

CO is the product of heart rate and stroke volume. Many dysrhythmias may adversely affect CO. If the heart rate is too low, CO may be compromised. If the heart rate is too fast, ventricular diastolic filling may be impaired, thus decreasing CO. Rhythm disturbances are common after cardiac surgery and may be divided into bradyarrhythmias and tachyarrhythmias; these categories are further divided into atrial and ventricular arrhythmias.

Bradycardia may lead to ventricular distention, increasing wall tension and decreasing coronary perfusion pressure, factors that may promote the development of ischemia and heart failure. A heart rate of 80 to 90 appears to be optimal, allowing adequate filling and preventing overdistention but not causing rate-related ischemia. Bradycardia may be corrected by pacing. In general, epicardial pacing wires are left in place after chest closure and are attached to an external pacemaker in the immediate postoperative period. If the dysrhythmia is sinus bradycardia, atrial pacing is usually optimal. The second most common cause of bradyarrhythmia after cardiac surgery is atrioventricular dissociation. The combination of atrial and ventricular leads allows atrioventricular pacing for managing dissociation. Synchronization of the atrioventricular interval between 0.1 and 0.225 seconds optimizes CO.⁴¹

AFib is the most common tachyarrhythmia. It occurs in 10% to 35% of patients after cardiac surgery, usually on the second or third postoperative day. Postoperative AFib is associated with increased morbidity and mortality and with longer, more expensive hospital stays.⁴² Independent predictors of postoperative AFib include advanced age, male sex, history of AFib, history of CHF, and pre-CPB heart rate greater than 100 beats/min.⁴³ Surgical practices such as pulmonary vein venting, bicaval venous cannulation, postoperative atrial pacing, and longer cross-clamp times also were identified as independent predictors of postoperative AFib. Patients who developed postoperative AFib had longer lengths of stay, both in the ICU and in the ward, compared with patients who did not develop the complication.

Although premature ventricular contractions are common, sustained ventricular arrhythmias are far less frequent. Severe ventricular arrhythmias occurring after cardiac surgery are related to ischemia, hypoxemia, hypovolemia, electrolyte abnormalities, effects of vasoactive drugs, or underlying preexisting cardiomyopathy.⁴⁴ In a series of 2100 cardiac operations, only 16 patients (0.8%) developed ventricular fibrillation or sustained ventricular tachycardia during an interval from 3 days to 3 weeks after surgery. Ten of these patients had undergone valve surgery.⁴⁵ Prognosis in these patients is dependent on the preoperative ventricular prognosis. In those with a left ventricular ejection fraction of less than 40%, the mortality rate may be as high as 75%.⁴⁶

Afterload

Ventricular afterload is the impedance to ventricular ejection during systole. Hypertension develops in as many as 60% of patients after surgery. Increased arterial blood pressure occurs even among patients without a preoperative history of hypertension. Predisposing factors include hypoxemia, hypercapnia, inadequate rewarming, pain, fluid overload, and increased sympathetic tone. Perioperative discontinuation of β -adrenergic blockers also may contribute to the development of postoperative hypertension. Hypertension and increased afterload may lead to myocardial ischemia by augmenting ventricular stroke work. Additionally, hypertension may lead to bleeding from surgical sites, aortic dissection, and increased risk of stroke.

Tamponade

Tamponade refers to the hemodynamic consequences of a collection of blood or other fluid in the pericardial sac. In postsurgical patients,

the presentation of tamponade may be subtle and differ significantly from classic descriptions. Equilibration of filling pressures typically is not seen. More commonly, patients present with isolated elevation of right atrial pressure caused by compression of the right atrium and superior vena cava. After cardiac surgery, as many as 66% of pericardial fluid collections are loculated posterior effusions.⁴⁷

Bleeding from the atrial cannulation site is a common cause of tamponade. As the pressure on the right atrium increases, ventricular filling is impaired, and CO decreases. Diagnosis of tamponade is made difficult by the high overall frequency of pericardial effusions after surgery. Echocardiographic studies have shown that moderate effusions are present in 30% of patients on the eighth postoperative day, with 2% of patients having large effusions.⁴⁸

Diagnosis of tamponade in the postoperative patient requires a high index of suspicion and prompt intervention. Any hemodynamic instability should be assessed for tamponade. Low CO, hypotension, and tachycardia accompanied by an elevation of the left, right, or both atrial pressures should lead to a prompt echocardiogram. Other signs that may be present include a widened mediastinum on chest radiography, dysrhythmias, and decreased ECG voltage. Because of the influence of positive pressure ventilation, the classic sign of pulsus paradoxus may not be present.

If time permits, the diagnosis of tamponade may be confirmed with the use of echocardiography. Although effusions are common, signs of compression or collapse of either atrium or right ventricle are diagnostic.⁴⁹⁻⁵¹ It is important to remember that the diagnosis may be made on clinical suspicion alone, and that treatment should not be withheld to await confirmation. Once tamponade is diagnosed, volume transfusion may temporize the situation. Pericardiocentesis is not effective in this situation, and prompt reexploration for hemostasis and evacuation of clot is indicated.

Respiratory Complications

Patients undergoing cardiac surgery are at risk for multiple pulmonary complications. These include PTX and pleural effusion in the immediate postoperative period. After the first 24 hours, patients sometimes develop acute lung injury (ALI), ARDS, or pneumonia. Diaphragmatic dysfunction secondary to phrenic nerve injury may occur.

Residual PTX is often seen on the initial postoperative chest radiograph and is commonly on the left side as a result of opening the left parietal pleura during dissection of the left internal mammary artery. The PTX usually resolves spontaneously as the chest tubes are placed on suction. Occasionally, a PTX is seen on the right side as a result of accidental incision of the right parietal pleura. Right PTX may progress to tension PTX and significant hemodynamic deterioration. This diagnosis should be considered in any unstable patient. Treatment consists of insertion of an additional chest tube.

Pleural effusion in the first 24 hours after cardiac surgery should raise the suspicion of hemothorax. Effusions should be watched carefully for expansion and correlated with other signs and symptoms of continued bleeding. Massive, expanding hemothorax is an indication for immediate reexploration and hemostasis. Pleural effusion after the first 24 hours is generally a benign process. Most pleural effusions resolve spontaneously. Thoracentesis should be performed only if the effusion occupies more than 50% of the lung field on radiography or if the patient has significant impairment of respiratory function.

ALI and ARDS are rare (<0.5%) complications after cardiac surgery, CPB, and blood transfusion. The mortality rate associated with this complication ranges between 15% and 70%.⁵² During the postoperative period, patients with ARDS were more likely to have had prior cardiac surgery or received more blood products and developed shock more frequently than patients without ARDS.⁵³

Nosocomial pneumonia may complicate any ICU stay. Patients who require mechanical ventilation for longer than 48 hours are at a particular risk. These pneumonias are usually caused by aspiration of oral or gastric secretions into the lungs. The incidence of nosocomial pneumonia may be reduced by diligent mouth care to prevent pooling

of secretions and elevation of the head of the bed to greater than 30 degrees. Nosocomial pneumonia carries a mortality rate of 24% to 50% and warrants appropriate broad-spectrum antimicrobial therapy.⁵⁴ Early broad-spectrum antibiotics (based on the cardiac ICU-specific antibiogram) should be initiated and then deescalated once the results of quantitative cultures are available.

Diaphragmatic dysfunction is usually caused by a cold-induced injury of the phrenic nerve as a result of the application of ice slush to the heart as part of the cardioplegia regimen. This complication occurs in up to 2% of patients undergoing cardiac surgery with topical hypothermia.^{55,56} While the patient is being ventilated with positive pressure, this injury will not be apparent. If preoperative pulmonary function was normal, unilateral diaphragmatic paralysis usually is well tolerated. Pulmonary function may be severely compromised if pulmonary problems were present preoperatively or if bilateral diaphragmatic injury occurs.⁵⁷ Such patients are at an increased risk of developing nosocomial pneumonia, failing to wean from the ventilator, and succumbing to death. Diaphragmatic dysfunction usually resolves spontaneously within 3 to 4 months.

Continued Bleeding

Continued bleeding is a common problem and requires immediate and aggressive management before the onset of further complications. The reasons for continued bleeding are often multifactorial and include inadequate surgical hemostasis, platelet dysfunction, coagulopathy, and inadequate heparin reversal. Often these factors occur in combination, and patients undergoing valve replacement are at an increased risk.⁵⁸

Multiple clotting abnormalities are possible, most of which result either directly or indirectly from the use of CPB.⁵⁹ The tubing, blood reservoir, and oxygenator membrane are all foreign surfaces that may activate the clotting cascade. Because the pump must be primed with either normal saline or lactated Ringer's solution, the priming process leads to substantial dilution of all blood components including red blood cells, platelets, and clotting factors. After CPB, the platelet count is decreased, and the remaining platelets are functionally deranged.^{60,61} There is sequestration of platelets in the liver, spleen, and CPB circuit itself. Systemic fibrinolysis due to activation of this system by the CPB circuit occurs.

Inadequate reversal of heparin should be diagnosed at the bedside by the activated coagulation test (ACT) or by measuring the activated partial thromboplastin time (APTT). Because the half-life of heparin is longer than that of protamine, heparin-induced anticoagulation may rebound in the immediate postoperative period. The treatment is administration of additional protamine.

Renal Dysfunction

Mild renal dysfunction is a common postoperative event (7%),⁶² with approximately 1% of patients diagnosed with acute renal failure (ARF) requiring renal replacement therapy. These patients have increased morbidity and mortality with prolonged ICU length of stay as much as fivefold.⁶²

A multicenter study of 2222 patients undergoing CABG identified 5 independent preoperative predictors of renal dysfunction: age 70 to 79 years or 80 to 95 years, CHF, previous myocardial revascularization, type 1 diabetes mellitus (DM) or preoperative serum glucose levels exceeding 300 mg/dL, and preoperative serum creatinine levels of 1.4 to 2.0 mg/dL. Independent perioperative factors that exacerbated risk were CPB lasting 3 hours or longer and various measures of ventricular dysfunction.⁶² The predominant predisposing factor appears to be low CO exacerbated by concurrent use of vasopressors such as phenylephrine.⁶³

Renal dysfunction tends to follow one of the three main patterns.⁶⁴ *Abbreviated ARF* (creatinine peaks on post-op day 4) is a transient event, most probably related to intraoperative renal ischemia. *Overt ARF* (creatinine peaks at a higher level than abbreviated ARF and then

decreases over weeks) occurs when the duration of the predisposing insult, usually low CO, is longer. *Protracted ARF* (frequently irreversible renal failure) occurs when a second insult, commonly sepsis or hypotension, is superimposed on the resolving renal function.

Neurologic Complications

Neurologic sequelae of CPB range from subtle neurocognitive deficits (appearing in up to 80% of patients) to stroke. To estimate the relative risks of neurologic sequelae associated with various clinical factors, a logistic regression model was applied to prospectively collected data from 273 patients enrolled at 24 American medical centers.⁶⁵ Adverse cerebral outcomes occurred in 16% of patients and were almost equally divided between type I (8.4%; 5 cerebral deaths, 16 nonfatal strokes, and 2 new transient ischemic attacks) and type II outcomes (7.3%; 17 new cases of intellectual deterioration persisting at hospital discharge and 3 cases of newly diagnosed seizure disorder). Resource utilization for these patients was significantly increased; median ICU stay was prolonged from 3 days to 6 to 8 days, and total duration of hospitalization was increased by 50% (type II outcomes) to 100% (type I outcomes). After discharge from the acute care setting, specialized care was required for 69% of the patients with adverse neurologic sequelae. Risk factors for type I outcomes related primarily to embolic phenomena including proximal aortic atherosclerosis, intracardiac thrombus, and intermittent clamping of the aorta during surgery. Risk factors for type II outcomes included, in addition to these factors, a preoperative history of endocarditis, alcohol abuse, perioperative dysrhythmia, poorly controlled hypertension, and low CO after CPB.

Gastrointestinal Complications

Acute abdominal complications are relatively rare after cardiac surgery. If they do occur, they are associated with extremely high rates of morbidity and mortality. One prospective study of 1116 patients undergoing CPB found that abdominal complications occurred in 23 (2.1%). Ten of these patients underwent subsequent abdominal surgery, and 20 died. Early complications occurred on postoperative days 6 and 7 and consisted of bowel ischemia or hepatic failure. These complications are probably related to perioperative hypotension and low CO.⁶⁶ Late complications consisted of pseudomembranous colitis, cholecystitis, pancreatitis, and rupture of a septic spleen.⁶⁷

Mild transient increases in circulating levels of hepatocellular enzymes are common after surgery. These changes are generally of no consequence; however, increased serum transaminase levels, if sustained or very high (e.g., serum alanine aminotransferase concentration >500 IU/L), may represent evidence of severe ischemic injury of the liver and carries a high risk of mortality. This complication is strongly associated with low CO and increased filling pressures, suggesting that liver ischemia is induced by a combination of decreased perfusion and venous congestion.⁶⁸

MANAGEMENT OF COMMON POSTOPERATIVE PROBLEMS

Optimization of Cardiac Output

Treatment of hypotension and low CO must be tailored to the cause. Again, it is useful to consider treatment in terms of preload, contractility, afterload, and rate and rhythm. Inadequate filling pressures are treated with volume infusion. The intravascular volume expander may be a crystalloid solution, a colloid solution, or packed red blood cells if hematocrit is low or there is evidence of ongoing bleeding. It is important to remember that inotropic therapy is ineffective and possibly detrimental if adequate blood volume is not restored.

If CO or blood pressure remains low despite intravascular volume resuscitation, then it is necessary to institute an inotropic or vasopressor support. No single agent is optimal in all cases. Rather, selection of the agent should be based on the suspected cause of low CO or

TABLE 157-2 Comparison of Relative Activity of Available Vasoactive Agents

| AGENT | α_1 | β_1 | β_2 | PHOSPHODI- ESTERASE INHIBITION | DOSE (mcg/kg per Minute) |

hypotension and knowledge of pharmacologic effects of the various inotropic and vasopressor drugs that are available (Table 157-2). If the primary cause of hypotension appears to be vasodilatation, administration of a vasoconstrictor (e.g., phenylephrine, norepinephrine, or vasopressin) is indicated. If hypotension is related to inadequate ventricular ejection, then inotropic therapy (e.g., epinephrine, norepinephrine, dopamine, or dobutamine) with a β -adrenergic agent should be instituted. In patients with chronic systolic dysfunction, response to these agents may be impaired. Chronically elevated levels of circulating catecholamines deplete myocardial norepinephrine stores and downregulate the expression of myocardial β -adrenergic receptors. In these patients, tachyphylaxis to β -adrenergic agonists may develop rapidly. Adding a phosphodiesterase inhibitor (e.g., amrinone or milrinone) is often effective in these patients.^{69,70} In all cases, agents should be titrated to achieve adequate end-organ perfusion.

Mechanical Support of the Circulation

Failure to respond to appropriate vasopressor or inotropic therapy may necessitate mechanical support of the circulation. IABP is the most commonly used method. The balloon is positioned in the aorta just distal to the take-off of the left common carotid artery. Inflation of the balloon during diastole increases the diastolic pressure above the balloon, thereby increasing the coronary perfusion pressure. Conversely, deflation during systole decreases the left ventricular afterload. This combination of hemodynamic effects ameliorates myocardial ischemia and improves CO.

Ventricular assist devices (VADs) are more effective than IABP for maintaining CO. Either the left ventricle or the right ventricle or both may be supported with VADs. Currently, VADs may be used either as a bridge to transplantation or as a bridge to recovery. Either situation assumes that the VAD is a time-limited intervention. There are some data to support the view that resting the heart through the use of a VAD may allow some recovery of acutely injured myocytes, permitting eventual withdrawal of mechanical support. If the heart is chronically diseased, there is little hope of recovery, and the VAD serves to support the patient until transplantation becomes possible.⁷¹⁻⁷³

Ongoing clinical trials are investigating the use of VADs as definitive therapy rather than as a bridge to transplantation. Implantation of these devices may increase the long-term survival of patients with end-stage heart failure.⁷⁴

Correction of Arrhythmias

AFib is the most commonly encountered arrhythmia after cardiac surgery. Prophylactic use of β -adrenergic blockers reduces the incidence of postoperative AFib, and they should be administered after cardiac surgery to all patients unless specific contraindications are present.⁷⁵ Prophylactic treatment with amiodarone and atrial overdrive pacing should be considered for patients who are at a high risk for

postoperative AFib (e.g., those with a history of previous AFib or mitral valve surgery).^{42,76}

If AFib develops after cardiac surgery, the intensivist needs to determine whether the primary strategy should be to control the ventricular rate or to restore normal sinus rhythm. If AFib is associated with hemodynamic instability or anticoagulation is contraindicated, rhythm management using electrical cardioversion or amiodarone is preferred.^{77,78} Overdrive pacing using atrial pacing wires also may be effective. The appropriate strategy for most stable patients may be control of ventricular rate, because most will spontaneously revert to sinus rhythm within 8 weeks after discharge.^{79,80} Appropriate agents to achieve ventricular rate control include intravenous or oral β -adrenergic blockers or calcium channel blockers. All patients with AFib persisting for longer than 24 to 48 hours should be anticoagulated unless there is a specific contraindication. Long-term outcomes are similar regardless of whether the rate-control strategy or the rhythm-control strategy is selected.^{81,82}

Postoperative ventricular arrhythmias should be treated immediately according to the current advanced cardiac life support protocols.²³ Any postoperative ventricular arrhythmia should prompt a search for an underlying cause. Importantly, ischemia should be ruled out. Patients with sustained ventricular arrhythmias should undergo electrophysiologic testing before long-term antiarrhythmic therapy is instituted. The implantable cardioverter-defibrillator device has been shown to be superior to drug therapy for patients with hemodynamically significant arrhythmias.⁸³

Hypertension in the Postoperative Period

Hypertension leading to an increase in ventricular afterload is a common cause of decreased CO. Hypertension may be controlled by an intravenous infusion of sodium nitroprusside, nitroglycerin, β -adrenergic antagonists, or calcium channel blockers. These agents should augment CO by reducing blood pressure and afterload in the hypertensive patient. Frequently, acute hypertension resolves within 24 to 48 hours postoperatively. If hypertension persists beyond this initial period of recovery, intravenous agents should be weaned and oral therapy initiated. Both β -adrenergic blockers and angiotensin-converting enzyme inhibitors have been shown to confer a long-term mortality benefit and should be started. If hypertension was not a problem preoperatively, prolonged antihypertensive therapy postoperatively usually will not be necessary.

Correction of Coagulopathy

Postoperative coagulopathy may promote bleeding and accumulation of blood in the chest or pericardial cavity. Aggressive measures must be used to correct the coagulopathy. A systemic approach to the evaluation and treatment of continued bleeding is needed; one such approach is outlined in Table 157-3. Hypothermia may contribute to coagulopathy. Therefore, profoundly hypothermic ICU patients must be actively rewarmed with the use of transcutaneous warming. Laboratory evaluation of suspected coagulopathy should include measurements of platelet count, prothrombin time (PT), APTT, ACT, and bleeding time. The use of thromboelastography (TEG) may be useful to guide component transfusion requirements.

Postoperative Bleeding

Bleeding that continues after correcting coagulopathy needs to be treated aggressively. Venous bleeding in the chest may be partially controlled by applying positive end-expiratory pressure (PEEP).^{84,85}

Continuing mediastinal hemorrhage, or the suspicion of cardiac tamponade, is an indication for immediate reexploration. Exsanguinating hemorrhage or impending arrest from tamponade may require that reexploration be carried out at the bedside in an ICU. Bleeding that is unresponsive to medical therapy and requires reexploration is usually associated with a surgical source. Accepted guidelines for reoperation include bleeding rates of 400 mL/h for 1 hour, 300 mL/h for 2 hours,

TABLE 157-3 Evaluation and Treatment of Postoperative Coagulopathy

| COAGULATION TEST | NORMAL RANGE | SUGGESTED TREATMENT |
|------------------|--------------------------|---|
| Body temperature | — | If less than 35.5°C, the patient should be actively rewarmed. |
| PT | 11-13.3 seconds | Administer fresh-frozen plasma. |
| PTT | 21-32 seconds | Consider additional protamine.* |
| Platelets | 140,000-440,000/ μ L | If <100,000, transfuse platelets. |
| Fibrinogen | 150-360 mg/dL | If <100, transfuse cryoprecipitate. |
| Bleeding time | 2.5-9.5 min | If prolonged and platelet count is normal, consider platelet dysfunction and treat with DDAVP and/or cryoprecipitate. |
| ACT | 90-120 seconds | Consider additional protamine.* |

*Excessive protamine may itself cause bleeding.¹⁰⁵

ACT, activated coagulation test; DDAVP, desmopressin acetate; PT, prothrombin time; PTT, partial thromboplastin time.

or 200 mL/h for 3 hours. A sudden decrease or total cessation of drainage from mediastinal tubes may be equally ominous. Cessation of drainage from a mediastinal or chest tube may be caused by clotted blood occluding the tube. If bleeding persists but drainage ceases, the result may be tamponade.

Reexploration is associated with increased morbidity and mortality. However, this increased mortality and morbidity may be partially explained by delays in the decision to reexplore that lead to avoidable open-chest resuscitations in the ICU.^{58,86,87}

Postoperative Renal Failure

The cornerstone of prevention and treatment of renal failure in the cardiac surgical patient is the maintenance of adequate renal perfusion. This goal is best achieved by optimizing circulating blood volume and CO. Multiple pharmacologic regimens for renal protection have been described. Dopamine at low “renal” doses (1-3 μ g/kg per minute) has been used. The rationale for this strategy is that dopamine activates type 1 dopaminergic (DA1) receptors, leading to renal artery dilation, natriuresis, and diuresis. However, numerous human studies have failed to show that low-dose dopamine prevents renal failure or improves survival.⁸⁸ Even low doses of dopamine increase CO, and this may be the basis for any increase in urine output observed.⁸⁹ Fenoldopam⁹⁰ and dexmedetomidine⁹¹ are DA1 receptor antagonists that have also been proposed as renal protective agents and used with mixed success.⁹²

Loop diuretics such as furosemide have been proposed as renal protective agents, not only because of their ability to produce diuresis and natriuresis but also because these drugs may reduce medullary tubular oxygen consumption. Mannitol, an osmotic diuretic, has been used to prevent the development of ARF. Neither mannitol nor furosemide has been shown to improve outcomes in patients with ARF.⁶² Indeed, these drugs may be deleterious because of their ability to promote diuresis and thus exacerbate hypovolemia and inadequate renal perfusion. Some success has been reported with the combination of mannitol, furosemide, and dopamine.⁹³ Infusing a solution containing these three agents promoted diuresis in patients with acute postoperative ARF and adequate CO and significantly decreased the need for dialysis in the majority of patients.⁹¹ Early administration of this solution in ARF caused early restoration of renal function to the normal or baseline status.⁹³

The failure of pharmacologic means of preventing and treating renal failure has led to interest in other methods. Early and intensive use of continuous venovenous hemofiltration achieved a better than

predicted outcome in a series of 65 consecutive patients with severe ARF who underwent cardiac operations.⁹⁴

Glucose Control

Studies have shown that tight control of blood glucose level in the ICU is associated with an increase in morbidity and mortality (Table 157-4). Hyperglycemia and insulin resistance are common in critically ill patients, even those who have not previously had DM. Results of a prospective randomized controlled study⁹⁵ in which 6104 critically ill adult patients were randomly assigned to receive either intensive insulin therapy (maintaining blood glucose concentration between 80 and 108 mg/dL) or conventional treatment (infusing insulin to keep blood glucose level 180 mg/dL or less) showed that, at 3 months, the intensive insulin therapy group had an increase in hypoglycemic episodes and ICU mortality.

Mechanical Ventilation

In uncomplicated recoveries, patients require only a short period of mechanical ventilation. Typically, volume-controlled ventilation is used until sedation is discontinued and the patient awakens. Once the patient is awake, hemodynamically stable, and without evidence of bleeding, a short trial of spontaneous ventilation is performed. If the weaning trial is successful, the patient is extubated. If continued mechanical ventilation is required because of respiratory failure or hemodynamic instability, either conventional volume-controlled ventilation or pressure support ventilation may be employed.

A small number of patients develop ALI or ARDS. In a large prospective trial of medical and surgical patients with ARDS or ALI, it was clearly beneficial to employ a lung-protective strategy (6 mL/kg ideal body weight) for mechanical ventilation.⁹⁶ No such study has been performed in cardiac surgical patients, but it seems reasonable to adopt the same guidelines. These recommendations apply only to patients with established ALI/ARDS; use of low tidal volumes has not been shown to be effective when used prophylactically.

Patients with ALI or ARDS typically require increasing levels of PEEP to support oxygenation. The effect of PEEP on ventricular output is controversial. There is evidence that the application of PEEP up to 30 cm H₂O decreases CO by reducing ventricular preload and displacing the interventricular septum toward the left, which restricts left ventricular filling.⁹⁷ Other studies have not supported this view. When adult patients with normal preoperative respiratory status were randomly assigned to treatment with graded degrees of PEEP between 0 and 10 cm H₂O during mechanical ventilatory support, there were no significant differences in cardiac index among the groups.⁹⁸ It is likely that the effects of PEEP on the circulation are widely variable among patients and that the appropriate strategy is upward titration of PEEP under close monitoring.

OUTCOMES OF CARDIAC SURGERY

Increasingly, health care is being driven by outcome data. Cardiac surgery has been one of the leading specialties in this field. It is difficult to assess results from crude mortality data, because these do not take into account case complexity and differing preoperative risks among patients. Crude comparisons of death rates may be misleading and may encourage surgeons to practice risk-averse behavior. Death rates should be stratified by risk. It is, however, possible to make some generalizations. Among low-risk patients undergoing CABG, mortality rates lower than 2% are achievable.⁹⁹ Higher mortality rates are to be expected in selected subgroups of patients with major preoperative risk factors (e.g., poor ventricular function, advanced age, and comorbid conditions) or major operative risk factors (e.g., reoperative surgery and complex operations).

A prospective cohort of 27,239 consecutive patients undergoing isolated CABG was examined to determine the risk factors for hospital mortality. After adjustment for patient and disease characteristics, the

TABLE 157-4 Protocol for Blood Sugar Control in the Postoperative Period

Decision to initiate IV insulin

If BG <200 mg/dL, begin D₅ ½ NS at 60-100 mL/h.

If BG >300 mg/dL, give stat dose of IV insulin, 0.1 U/kg body weight.

Initiate an hourly rate (total daily dose of insulin divided by 24).

For patients who have never taken insulin, give 0.02 U/kg body weight per hour.*

Check BG hourly and adjust according to the following table.

Recheck BG hourly.

If in desirable range (101-150 mg/dL), continue to check BG every 2 hours and adjust as necessary.

| CURRENT BG (mg/dL) | PREVIOUS BG (mg/dL) | | | | | | | |
|--------------------|---|---------------------------------------|-------------------------------------|---------------------------------------|---------|-------------------------------------|-------------------------------------|-------------------------------------|
| | <60 | 60-80 | 81-100 | 101-150 | 151-200 | 201-250 | 251-300 | 301-400 >400 |
| <60 | Withhold drip and give 1 ampule of 50% glucose; check BG every 30 min until >100 mg/dL, then reinitiate drip at 50% of previous rate. | | | | | | | |
| 60-80 | Withhold drip; check BG every 30 min until >100 mg/dL, then reinitiate drip at 50% of previous rate. | | | | | | | |
| 81-100 | ↓ Rate by 1 U/h | No change | | ↓ Rate by 25% or 0.5 U/h [†] | | ↓ Rate by 25% or 1 U/h [†] | | ↓ Rate by 50% or 2 U/h [†] |
| 101-150 | No change | | | ↓ Rate by 25% or 1 U/h [†] | | | | |
| 151-200 | ↑ Rate by 1 U/h | ↑ Rate by 0.5 U/h | | ↑ Rate by 25% or 1 U/h [†] | | No change | | ↓ Rate by 25% or 1 U/h [†] |
| 201-250 | ↑ Rate by 25% or 2 U/h [†] | | ↑ Rate by 25% or 1 U/h [†] | | | ↑ Rate by 1 U/h | | No change |
| 251-300 | ↑ Rate by 33% or 2.5 U/h [†] | ↑ Rate by 25% or 1.5 U/h [†] | ↑ Rate by 25% or 1 U/h [†] | ↑ Rate by 1 U/h [†] | | ↑ Rate by 1.5 U/h [†] | ↑ Rate by 25% or 2 U/h [†] | No change |
| 301-400 | ↑ Rate by 40% or 3 U/h [†] | | | | | | | |
| >400 | ↑ Rate by 50% or 4 U/h [†] | | | | | | | |

BEFORE DISCONTINUING INSULIN INFUSION

Ensure that the patient is able to tolerate oral intake.

Write orders for alternative glycemic management.

Precede discontinuation by 1-2 hours with subcutaneous dose of very rapid or rapid insulin. If patient has never taken insulin, use a dose equal to twice the hourly rate of IV insulin. Otherwise, use the dose of insulin or oral agent given before surgery/admission.

*For patients undergoing major surgery (e.g., cardiothoracic surgery, transplantation), higher doses may be necessary.

[†]Whichever is greater.BG, blood glucose concentration; D₅ ½ NS, 5% dextrose in half-normal saline; IV, intravenous; U, units.

following comorbid conditions were found to be related to postoperative mortality: DM, vascular disease, chronic obstructive pulmonary disease, peptic ulcer disease, and dialysis-dependent renal failure.¹⁰⁰

Cardiac surgery is being performed more frequently in patients aged 80 years and older. In one study, the 30-day mortality rate for patients aged 65 to 75 years was 3.4% and for those older than 80 years was 13.5%. Older patients had longer ICU and postoperative lengths of stay. Although emergency operations and complex procedures carry high risks for octogenarians and increasing costs for the society, most of these patients may be offered operation with short-term morbidity, mortality, and resource use that only modestly exceed those of younger patients.¹⁰¹ Once discharged from the hospital, older patients report a high quality of life.¹⁰²

Overall, fewer than 10% of cardiac surgical patients spend more than 48 hours in the ICU. Most survive and eventually report improved functional status and a reasonable quality of life.^{103,104}

CONCLUSION

Most cardiac surgical patients may be discharged from the ICU to a step-down unit within 24 to 48 hours after operation, but an increasing number cannot. Patients who require longer and more intensive services in the ICU are typically older and sicker preoperatively. Adherence to best practices in the ICU optimizes the opportunity for even these high-risk patients to survive their operation and achieve a good quality of life after hospitalization.

The ongoing development of less invasive techniques in cardiology and cardiac surgery will, paradoxically, bring about a further increase in the complexity of cases treated in the cardiac surgical ICU as patients who are less sick are treated elsewhere. This trend will lead to increasing challenges for intensivists working in these units and allow them to continue to be at the forefront of critical care medicine.

KEY POINTS

1. Developments in interventional cardiology have led to older and medically complex populations being referred for cardiac surgery.
2. Much of the care of cardiac surgical patients should be protocol driven and conducted in specialized units.
3. Most patients undergoing cardiac surgery require only a shorter ICU stay.
4. Patients may be extubated once hemodynamic stability is achieved and mediastinal bleeding is deemed to be under control.
5. Low CO after surgery should be treated based on the components of the CO: rate, rhythm, preload, afterload, and contractility.
6. AFib continues to be a cause of significant morbidity.

OVERVIEW OF LUNG TRANSPLANT

Lung transplantation offers hope for improved survival and quality of life for selected patients with end-stage lung disease. The availability of suitable donor organs and preservation injury remain the initial limiting factors to successful transplantation. Novel techniques aiming to extend the donor pool have resulted in the ability to offer transplantations to more patients both by allowing for better evaluation of questionable organs as well as by allowing potential treatment and repair of injured organs.^{1,2} Like other solid organ transplants, rejection and infection, as well as organ system dysfunction associated with the perioperative course, remain challenges.³ However, over 40 years of experience has led to substantial improvements in early outcome. This experience has been reflected in changes in various aspects in the field, including a different allocation system where priority is given based on medical urgency and expected outcome,⁴ donor and recipient assessments, innovative surgical techniques, better understanding of early complications, and the development of newer immunosuppressive medications.

Diagnoses for which adults undergo lung transplantation include chronic obstructive lung disease (COPD) from emphysema (32%), interstitial lung disease (24%), cystic fibrosis (16%), alpha-1 antitrypsin deficiency (5%), and others including sarcoidosis, congenital heart disease, and connective tissue disease complicated by advanced lung disease.³ Over the past 2 decades, the number of single lung transplant (SLT) procedures has remained stable, and the number of bilateral lung transplant (BLT) procedures has seen a steady increase. In recent years, most recipients who had the most common indications for lung transplantation underwent bilateral procedures, with COPD, either from emphysema or alpha-1 antitrypsin deficiency, being the most frequent diagnosis of transplantation. This has been the scenario where the trend toward bilateral transplantation has been more noticeable.³

Donor selection, procurement, and lung preservation protocols tend to be individualized on an institutional basis. The limited availability of donor lungs, however, has increased the scrutiny with which organs are judged in order to avoid rejecting them inappropriately. Significant lung contusion, smoking-related lung damage, pneumonia, pulmonary edema, and significant aspiration are prime concerns in evaluating the suitability of donor organs. Although already described as an independent association for primary graft dysfunction (PGD),⁵ donor's older age is being challenged at some centers as a risk factor for worsened outcomes. More transplants have been performed where the donor does not meet stringent criteria.⁶ Procurement and lung preservation protocols often include administration of antiinflammatory agents, pulmonary vasodilators, and antioxidants.

The surgical technique involves thoracotomy for SLT or transverse thoracosternotomy (clamshell incision) for BLT transplants. Minimally invasive techniques are being developed in some centers as well. The surgical procedure includes anastomoses of the pulmonary artery, atrium, and bronchus. Cardiopulmonary bypass (CPB) is avoided in the case of SLT and BLT, unless preexisting pulmonary hypertension precludes cross-clamping of the pulmonary artery or if cardiorespiratory stability cannot otherwise be maintained. On completion of the operation, a double endotracheal tube (EBT) is exchanged for a standard endotracheal tube (ETT), unless allograft function appears tenuous or there is evidence of air trapping. Heart-lung transplants are

performed utilizing either a clamshell incision or sternotomy. CPB is obviously a requirement in these patients. The vascular anastomoses include the aorta and a cuff of right atrium including both vena cavae. Bi-bronchial airway anastomoses, which are associated with less dehiscence than a single tracheal anastomosis, are performed.

MANAGEMENT OF CRITICALLY ILL LUNG TRANSPLANT CANDIDATES—BRIDGE TO LUNG TRANSPLANT

In recent years, the proportion of candidates requiring support beyond noninvasive measures including mechanical ventilation and extracorporeal life support (ECLS) has increased, resulting in a larger proportion of patients requiring intensive care management and support before transplantation.⁷

The field has learned that, in large-volume centers,⁸ outcomes are unaffected and that the technology around ECLS support has evolved to become simpler.⁹⁻¹² Technologic advances include heparin-coated circuits, development of polymethylpentene oxygenator membranes, introduction of centrifugal pumps, dual lumen cannulas, and miniaturized systems. Although these have translated into an increased interest toward the earlier implementation of ECLS, its use has been described as a risk factor for airway dehiscence, stroke, infection, and thromboembolic complications after transplantation.¹¹ Efforts toward ECLS without mechanical ventilator support—"awake ECLS"—aim to offset the risks of prolonged sedation and subsequent postoperative deconditioning.¹³ Awake ECLS has resulted in improved early outcomes.¹³

Intraoperative Issues

The choice of the type of surgical incision (clamshell incision vs. anterolateral thoracotomies vs. median sternotomy) for lung transplantation depends on several factors, which include single or bilateral lung transplantation, CPB use, history of prior surgery in the recipient, and surgeon's preference. Bilateral anterior thoracotomy (sternal sparing) performed for BLT has a lower rate of sternal infections and healing complications than clamshell incision.¹⁴ During surgery, three anastomoses are made on each side. From posterior to anterior, they include the bronchus, pulmonary artery, and pulmonary veins to the left atrium. Bronchial artery anastomosis is usually not made. In addition, lymphatic and nerve ending anastomoses are not made. About 30% to 40% of patients require CPB support, intraoperatively for hemodynamic instability or hypoxemia that occurs after clamping the first or second pulmonary artery. CPB is commonly required in recipients with pulmonary hypertension or in situations where independent lung ventilation is not possible.¹⁵ The tubing, cannulae, membrane oxygenators, and pumps used in the CPB machine trigger a systemic inflammatory response, and patients tend to be hypotensive from the resulting vasoplegia. Intraoperative extracorporeal membrane oxygenator machines have several advantages. They decrease the amount of circuit, thus decreasing the blood-air interface. There are a fewer number of blood products that are transfused and a lower incidence of PGD.¹⁶ At the conclusion of the surgery, the double-lumen endotracheal tube used for independent lung ventilation is changed to a

single-lumen tube. The patient is transferred to the intensive care unit (ICU) after chest closure. The patient is then weaned off of the ventilator and/or extracorporeal membrane oxygenation (EMCO) in the ICU.

Lung transplant recipients who have pulmonary hypertension require special attention. During surgery, every effort is made to prevent a sudden rise in pulmonary pressure that may cause right ventricular failure. Intraoperative transesophageal echocardiography (TEE) helps monitor the right ventricular function very closely. Inhaled nitric oxide (iNO), inhaled prostacyclin, and intravenous milrinone are used to support right ventricular function intraoperatively and during the immediate postoperative period.¹⁷

Immediate Postoperative Intensive Care Unit Management

Weaning the patient off of the mechanical ventilator and ECMO is performed by the ICU physician who works in close collaboration with the thoracic surgeon.¹⁸ Stabilization of respiratory function and ventilator weaning are the initial goals when the patient arrives in the ICU from the operating room. Either pressure or volume target ventilation is used. The goal is to keep the airway pressures low to avoid barotrauma to the fresh bronchial anastomoses and prevent atelectasis. Lung protective ventilation strategy with tidal volumes (VT) around 6 mL/kg of predicted body weight and low to moderate PEEP (positive end-expiratory pressures) should be used.¹⁹ High PEEP should be avoided. In patients who undergo SLT, it might be challenging to ventilate the graft as the compliance of the native lung will be different. Care should be taken to avoid overinflation of the native emphysematous lung as this might lead to hemodynamic compromise from auto-PEEP or intrinsic PEEP. Patients typically present with hypoxemia, hypercapnia, and hemodynamic instability. Decreasing the respiratory rate, increasing the expiratory time, and decreasing the PEEP can help. If the above measures do not help, brief disconnection from the ventilator circuit should be considered. If the situation continues, placement of a double lumen tube and independent lung ventilation should be considered.²⁰ Likewise, the compliance of the native fibrotic lung will be worse when compared to the new graft. This might risk overinflation of the new transplanted allograft. Mild pulmonary edema is a common finding in transplanted lungs due to the absence of lymphatic drainage. This usually clears up in the first few days. If end organ perfusion is adequate, increase in preload is avoided.^{19,21} iNO is routinely used in patients with pulmonary hypertension and right ventricular failure in the operating room. However, the intraoperative use of iNO does not seem to decrease the incidence of PGD.^{22,23} The patient is rapidly weaned from iNO in the ICU. As soon as clinical stability is achieved, weaning from the mechanical ventilator is started. The oxygen fraction is rapidly decreased, if tolerated.¹⁹ The majority of the patients will be weaned and extubated within the first 24 hours.^{20,23} Early extubation minimizes the chance of pulmonary infections and stress on the bronchial anastomoses. Patients can be extubated to noninvasive positive pressure ventilation (NIPPV). This helps in unloading of the respiratory muscles, decreasing respiratory rate, dyspnea, and improving ventilation/perfusion mismatch. NIPPV can also be used in recipients who demonstrate phrenic nerve dysfunction.²⁴ For patients requiring prolonged mechanical ventilation, a complicated postoperative course should be considered for early tracheostomy.²⁴ If there is difficulty in liberating from the mechanical ventilator, early tracheostomy should be considered as this would minimize sedation and help with physical therapy while providing easier access for secretion clearance.¹⁵ Patients who require reintubation can also be considered for tracheostomy. In debilitated patients, early tracheostomy may provide considerable benefit if prolonged mechanical ventilation is required. If patients cannot be extubated, the decision to perform a tracheostomy should be made early on in the first week.²⁵ Although lung transplant recipients who end up with a tracheostomy tend to be sicker, have a longer ICU stay, and be on prolonged ventilation, there is no difference in their short- and long-term survival compared to recipients who do not have a tracheostomy.

Tracheostomy in this population is an important option that enables weaning from the mechanical ventilator and is associated with better patient tolerance.²⁶ An early tracheostomy decreases the use of sedation and helps with weaning, mobilization, and physical therapy.²⁵ Chest tube removal depends on the 24-hour drainage from each tube. Apical chest tubes are removed first, followed by the basilar tubes, provided their drainage is less than 150 mL/24-hour period.¹⁵ Vigorous airway clearance techniques to mobilize secretions are an essential component of the recovery process after extubation. These include bronchodilators, incentive spirometry, flutter valve, chest physiotherapy, and nebulized hypertonic saline.

Pain control is an essential component of the postoperative ICU care. Adequate analgesia is essential to prevent splinting of the chest that would cause atelectasis. Fentanyl infusion and patient-controlled analgesia pumps are used once patients are more awake. Morphine is avoided as the patients' creatinine clearance tends to fluctuate with the initiation of calcineurin inhibitors, and there is a risk of accumulation of toxic metabolites of morphine. During surgery, patients undergo stretching of thoracic joints, ribs, vertebrae, and muscles; manipulation of pleura and lungs; and placement of chest tubes. All of the above cause considerable amount of pain when patients wake up from anesthesia. Poor pain control prevents patients from coughing and expanding the graft, thus increasing the risk of pulmonary complications. Moreover, the transplanted lungs are denervated and lack the cough reflex. Patients tend to splint from pain and as a result, diaphragmatic excursions are prevented, further causing retention of mucus that leads to atelectasis. Thoracic epidural analgesia is used for unilateral or bilateral thoracotomy. Epidural analgesia also decreases opiate requirements, thus decreasing sedation from opiates and enabling patients to participate more in mobilization and physical therapy.²⁷ An oral regimen consisting of oxycodone is started once patients are extubated and able to tolerate oral medications. Nonsteroidal antiinflammatory drugs are avoided for analgesia as they tend to worsen renal function, especially in patients who are on tacrolimus or cyclosporine.

Immunosuppression

Immunosuppression is initiated in the operating room. The first dose of an induction agent, like basiliximab (used in our center), is administered on the day of surgery. The second dose is repeated on the fourth postoperative day. The first dose of solumedrol (10 mg/kg) is administered just before perfusion of the first graft. This is followed by 1 g of intravenous mycophenolate mofetil. Tacrolimus is initiated after the arrival of the patient in the ICU. This practice might vary slightly from one center to another.

The main immunosuppressive drugs after transplantation include a combination of calcineurin inhibitors (tacrolimus or cyclosporine), antimetabolites (mycophenolate mofetil or azathioprine), and steroids. Calcineurin inhibitors are the cornerstone of the regimen. We default all patients to tacrolimus, mycophenolate mofetil, and prednisone. The dose of tacrolimus is gradually titrated to a tacrolimus trough level of 10 to 14 ng/mL, while monitoring the serum creatinine levels closely. Mycophenolate mofetil is administered at a dose of 1 g twice daily while cautiously monitoring for cytopenias.

Antimicrobials

Broad-spectrum antibiotics that would cover gram-positive and gram-negative organisms are initiated prior to making skin incisions on the recipient. Typical antibiotics include a combination of vancomycin and cefepime. Donor bronchus culture and prior cultures from recipient sputum guide the types and duration of the antibiotics. Trimethoprim-sulfamethoxazole, a prophylaxis against *Pneumocystis jiroveci* is started and given three times a week. Antifungal prophylaxis depends on pretransplant risk factors for aspergillus. Recipients with cystic fibrosis and cavitary disease are thought to have a high risk and are prophylaxed with oral voriconazole or posaconazole and inhaled

amphotericin. Patients who are at low risk for aspergillosis are prophylaxed with itraconazole. The oral prophylaxis is continued for 3 months. CMV prophylaxis depends on the CMV serologic status of the donor and recipient. If the donor is positive and the recipient is negative (D+/R−, CMV mismatch), the recipient is prophylaxed with daily valcyte. If the donor is CMV negative and the recipient is CMV positive (D−/R+) or if the donor and recipient are CMV positive (D+/R+), (intermediate-risk group) the recipient is prophylaxed with valcyte for 6 to 12 months. If the donor and recipient are CMV negative (D−/R−, low-risk group), the recipient is prophylaxed with acyclovir, which is effective against all herpesviruses other than CMV.

General Measures

Patients tend to get constipated from immobilization and opiate analgesics used in the immediate postoperative period. This is prevented by instituting scheduled laxatives. Constipation and ileus also interfere with absorption of immunosuppressive medications. Hence, great care is taken to prevent constipation and the slowing of gut motility. This is especially true in patients with cystic fibrosis who might require more aggressive measures that include osmotic laxatives, in addition to stimulant laxatives.¹⁸ On a similar note, electrolyte imbalance could make constipation and ileus worse. Magnesium, calcium, potassium, and creatinine levels need to be monitored closely. Hypomagnesemia results from the use of tacrolimus, proton pump inhibitors, and diuretics in the initial postoperative period. Intracellular levels of magnesium might be lower despite normal serum levels. This should be aggressively corrected to minimize neurotoxicity and cardiac dysrhythmias. Magnesium is a cofactor in muscle function and gastrointestinal motility.¹⁸ The incidence of venous thromboembolism in lung transplant recipients is much higher than in other populations. In fact, it is thought to be between 8% and 29%. As a result, deep vein thrombosis prophylaxis is enforced as soon as possible with low-molecular-weight heparin.²⁸

Lung transplant recipients have a high risk of gastroesophageal reflux from underlying esophageal dysmotility and recent thoracic surgery. Measures to control acid reflux and aspiration include keeping the head end of the bed elevated at a 30-degree angle or more and using a proton pump inhibitor.

Early and aggressive physical therapy is crucial in the success of lung transplantation to avoid critical care illness polyneuromyopathy. Once patients are extubated, they are mobilized to sit in a chair, twice a day. If patients are able to achieve adequate analgesia, they are made to walk with assistance.

POSTOPERATIVE COMPLICATIONS

Infectious Complications

Infectious complications are higher in lung transplant recipients compared to other solid organ transplantations. This is most likely related to the fact that the allograft is exposed to the environment. Moreover, a greater magnitude of immunosuppression is used in lung transplantation.²⁹ Bacterial infections of the lower respiratory tract are the most common infectious complications. The risk factors for these include immunosuppressed status, mechanical ventilation, and blunted cough due to pain.

Bleeding Issues

Increased bleeding is seen in recipients who have had previous pleurodesis and use of intraoperative or preoperative extracorporeal circulation (ECMO/CPB). Coagulopathy should be rapidly corrected with the transfusion of blood products. If there is increased bloody chest tube drainage of more than 200 mL/30 min, exploratory surgery should be considered. Even if the source of bleeding is not identified, the evacuation of blood products prevents collapse of the graft and development of the compartment syndrome.¹⁹

Acute Renal Failure

Acute renal failure is a common complication due to the use of calcineurin inhibitors. It results from intense afferent arteriole vasoconstriction caused by tacrolimus or cyclosporine resulting in decreased renal blood flow and glomerular filtration rate. Presence of systemic hypertension further worsens renal function. Hence, blood pressure should be well controlled, preferably with calcium channel blocking agents.^{15,29} Nonsteroidals should be avoided for analgesia. Diuretics should be used sparingly.

Atrial Tachyarrhythmias (Atrial Fibrillation, Atrial Flutter, and Supraventricular Tachycardia)

Atrial tachyarrhythmia is common in this population and occurs in 34% to 47% of the patients.¹⁵ The incidence is higher in double lung transplants than in single lung transplants and tends to occur 3 to 7 days after surgery. The incidence is also higher in older patients, patients who had been on CPB, and patients who had atrial manipulations. Electrolyte imbalance, sympathetic stimulation from pain, and anxiety precipitate atrial fibrillation. Rate control with beta blockers is preferred. Antiarrhythmic drugs are used if patients fail to respond to initial treatment. Amiodarone, sotalol, and propafenone have been used by different centers.³⁰⁻³²

Phrenic Nerve Injury and Diaphragmatic Paralysis

Phrenic nerve injury and diaphragmatic paralysis are underdiagnosed complications, with an incidence ranging from 3% to 40%. Difficulty weaning from the ventilator or thoracoabdominal asynchrony during spontaneous breathing trials, and a disproportionate elevation of the hemidiaphragm on postoperative chest X-rays should raise suspicion for this complication. Patients might also be hypercapneic on arterial blood gases. The diagnosis can be confirmed on a chest ultrasound or fluoroscopy when the recipient is breathing spontaneously. Absence of hemidiaphragmatic movement further confirms the diagnosis. Diaphragmatic weakness causes prolonged mechanical ventilation and increased length of hospital stay.¹⁹

Gastroparesis and Gastroesophageal Reflux

Vagal nerve injury during surgery might result in gastroparesis and gastroesophageal reflux. Patients might experience delayed gastric emptying, early satiety, epigastric fullness, nausea, vomiting and worsening acid reflux. Acid reflux increases the risk of microaspiration and injury to the new graft and can cause acute rejection. Hence, in the immediate postoperative recovery in the ICU, it is important to be vigilant of this complication. The head end of the bed has to be kept elevated to prevent aspiration. Likewise, prokinetics like azithromycin and metoclopramide are administered for gastroparesis until there is spontaneous recovery.¹⁹

Thrombotic Microangiopathy

Thrombotic microangiopathy is a life-threatening complication caused by small-vessel microthrombi. It results from endothelial injury, microcirculatory thrombosis, fibrin deposition, and platelet consumption. Microangiopathic hemolytic anemia, renal failure, thrombocytopenia, fever, and neurologic abnormalities are seen. This occurs due to tacrolimus or cyclosporine and is common in the first 3 months after transplantation.¹⁵ Incidence of thrombotic microangiopathy from calcineurin inhibitors is thought to be between 3% and 4.5%.³³ Low levels of ADAMTS-13 are not found in calcineurin-induced thrombotic microangiopathy, which is in sharp contrast to classic thrombotic thrombocytopenic purpura (TTP). Treatment includes discontinuation of the offending calcineurin inhibitor. Once the condition

improves, another calcineurin inhibitor can be attempted under close monitoring.

Hyperammonemia

Hyperammonemia occurs from a deficiency in hepatic glutamine synthetase, a urea cycle enzyme that plays an important role in processing nitrogenous waste.²⁹ This is a fatal complication that occurs in the first 30 days after transplantation. Symptoms include encephalopathy, lethargy, agitation, seizure, tremors, and coma.²⁹ Risk factors include total parenteral nutrition (TPN), lung transplantation for primary PAH. Treatment includes discontinuation of TPN, lactulose, neomycin, and aggressive hemodialysis.¹⁵

Bronchial Necrosis and Dehiscence

Bronchial circulation is not established during transplantation. Perfusion to airways and parenchyma is solely dependent on the blood supply from pulmonary arterial circulation. Pulmonary artery blood supply may be insufficient during the perioperative period, especially when vasopressors are used for hypotension. This might result in ischemic injury to the anastomosis or post anastomotic bronchus.³⁴ Relative ischemia exacerbated by intra- or postoperative hypotension and hemodynamic fluctuations makes anastomoses susceptible to necrosis, dehiscence, and infection. Severity of necrosis varies from commonly encountered mild focal necrotic sloughing to extensive necrosis, perforation, and bronchial dehiscence.³⁴ This usually occurs 1 to 5 weeks post operation with an incidence of 1% to 10%.³⁵ Hence, anastomosis should be examined carefully during every bronchoscopy. Clinical features include dyspnea, pneumomediastinum, subcutaneous emphysema, pneumothorax, lung collapse, and persistent air leaks in the early posttransplant period.³⁶ Since chest x-rays are unreliable, if bronchial dehiscence is suspected, computed tomography (CT) of the chest should be considered as it will very clearly delineate the bronchial defects and extraluminal air around the anastomosis.³⁴ Placement of self-expanding metallic stents that provoke granulation tissue can be used for healing.^{34,35}

Pulmonary Arterial Stenosis

Patients present with hypotension and evidence of severe right heart failure. This mimics a pulmonary embolism and can be treated with surgical correction or stent placement.

Pulmonary Vein Stenosis/Pulmonary Venous Obstruction

Pulmonary venous obstruction after lung transplantation is a very rare complication. It is associated with high morbidity and mortality unless recognized very early in the postoperative period. Patients present with progressive hypoxemia and infiltrates in the graft on chest x-ray, and it mimics acute pulmonary edema. Respiratory secretions in the endotracheal tube could be frothy pink or hemorrhagic. The pulmonary capillary wedge pressure could be high. This condition is diagnosed with TEE. The severity of the hypoxemia depends on the number of lungs transplanted, if pulmonary venous obstruction is unilateral or bilateral, and if the recipient had prior pulmonary hypertension. In patients who have undergone SLT and have prior pulmonary hypertension, pulmonary venous stenosis in the graft will cause severe hypoxemia and graft failure very early on. Bedside TEE is a very helpful tool to detect this condition. CT angiography is another option. Once diagnosed, patients need to be taken back to the operating room for reconstruction of the venous anastomoses.³⁷

Thoracic Compartment Syndrome

Thoracic compartment syndrome is seen in the immediate postoperative period, either immediately after chest closure or several hours

later. Patients present with hemodynamic instability. This complication is common in BLT, especially if there is a prolonged intraoperative course and transfusion of multiple blood products and/or use of CPB. Clinical features include high ventilator pressures, refractory hypotension, and progressive acidosis. Worsening lactic acidosis, tissue perfusion, renal function, and urine output are also noted. Immediate thoracotomy and delayed closure are recommended.³⁸

IMMUNOLOGIC CAUSES OF ALLOGRAFT DYSFUNCTION AFTER LUNG TRANSPLANTATION

Immunologic causes of allograft dysfunction after lung transplantation can be classified as immediate post-lung transplant complications (hyperacute rejection), within the first 72 hours after the transplant (PGD), and later events such as acute rejection (acute cellular rejection [ACR] and antibody-mediated rejection [AMR]), and chronic lung allograft dysfunction (CLAD). Other causes of allograft dysfunction such as infection, vascular anastomotic complications, and bronchial anastomotic complications have been discussed elsewhere.

Primary Graft Dysfunction

PGD is a form of acute lung injury that occurs within the first 72 hours after lung transplantation and is triggered by ischemia-reperfusion injury. PGD manifests as progressive hypoxemia and the presence of radiographic pulmonary infiltrates without other identifiable causes such as cardiogenic pulmonary edema, pneumonia, hyperacute rejection, or pulmonary venous anastomotic obstruction. It affects 10% to 35% of lung allograft recipients and is the major cause of early morbidity and mortality after lung transplantation.³⁹ In addition, PGD has been associated with an increased risk of CLAD, which is the major cause of late mortality after lung transplantation.⁴⁰

In 2005, the International Society of Heart and Lung Transplantation (ISHLT) Working Group on PGD proposed a standardized definition and grading system based on radiographic pulmonary infiltrates. A $\text{Pao}_2:\text{Fio}_2$ (P:F) ratio assessed immediately after lung transplantation (T0) and at 24 hours (T24), 48 hours (T48), and 72 hours (T72) post transplantation was suggested (Table 158-1).⁴¹ Subsequent validation studies using the standardized definition of PGD demonstrated a better discrimination of grade 3 PGD to predict early mortality. Grade 3 PGD at T72 accounted for 50% of all-cause mortality within the first 30 days post transplantation and demonstrated the most robust association with early and overall mortality after lung transplantation compared to the other grades of PGD.⁴²⁻⁴⁵

Prior studies have proposed several risk factors for the development of PGD based on the donor, recipient, and surgical variables (Table 158-2). Some of these risk factors are potentially modifiable (e.g., Fio_2 at reperfusion, obesity, cold ischemia time) and thus may suggest preventative strategies.⁴²

The pathogenesis of PGD is not well understood. The underlying etiology is thought to be an inflammatory cascade initiated by ischemia-reperfusion injury after lung transplantation, which ultimately leads to activation of the innate immune system and an influx of neutrophils into the lungs.^{49,50} During the past decade, several strategies targeting putative pathways in PGD have been studied, such as the use of iNO, modulation of the complement cascade, instillation of surfactant, and more recently, prevention of neutrophil extracellular traps (NETs) formation using an antiplatelet agent or intraalveolar disruption of NETs using DNase I.⁵¹⁻⁵³

Currently, the therapy for PGD remains generally supportive and draws from therapies applied in patients with ARDS, including lung-protective ventilation strategies. Additionally, pressure-controlled ventilation modes may be utilized to minimize barotrauma and airway anastomosis complications. Diuresis should be initiated, with blood pressure support, if needed, and excess fluid administration should be avoided.⁵⁴ Despite the encouraging results with iNO administration to

TABLE 158-1 2005 ISHLT Primary Graft Dysfunction Taxonomy

| GRADE AT T0, T24, T48, T72 | RADIOGRAPHIC INFILTRATES CONSISTENT WITH DIFFUSE PULMONARY EDEMA | PAO ₂ :Fio ₂ | SPECIFIC EXCEPTIONS |
|----------------------------|--|------------------------------------|--|
| 0 | — | Any | |
| 1 | + | >300 | On nasal cannula or Fio ₂ < 0.3 |
| 2 | + | 200-300 | |
| 3 | + | <200 | Any patients on ECMO or on NO with Fio ₂ > 0.5 MV |

prevent and treat severe PGD suggested by several animal studies and case series,⁵⁵⁻⁵⁸ randomized, controlled studies did not support efficacy for iNO use in the clinical setting.^{22,59} However, despite the lack of an established role for iNO in prevention or treatment of PGD, its use may be justified as salvage therapy in selected cases for improving oxygenation, reducing mean pulmonary arterial pressure, and increasing mean systemic arterial pressure early after transplant.⁶⁰

Institution of venovenous (VV) ECMO in patients with profound respiratory failure due to PGD has gained in popularity with potentially good survival, if started early.^{61,62} In cases with refractory respiratory failure, retransplantation has been performed. However, predicted survival is poor, and it is generally not recommended.^{54,63}

Acute Rejection

Acute rejection after lung transplantation is common and continues to affect approximately 40% of lung transplantation recipients in the first year post transplantation.⁶⁴ The clinical manifestations are variable, nonspecific, and potentially confounded by coexisting diseases and processes. The presentations range from being asymptomatic with no radiographic changes, detected via routine posttransplantation surveillance biopsies, to a clinical picture resembling ARDS.⁶⁵ Acute rejection after lung transplantation encompasses ACR and AMR.

Acute Cellular Rejection

ACR is the result of an immune reaction against donor antigens that are expressed on the surface of donor cells and recognized by recipient lymphocytes. Recipient lymphocytes can react to various donor antigens such as blood group antigens and human leukocyte antigens (HLAs). HLAs are highly polymorphic cell-surface molecules and can

lead to a robust immune response when mismatched between donor organ and recipient. The lung is a rich lymphoid organ and possesses all immune cell lines necessary for initiation and maintenance of an immune reaction. Shortly after transplantation, the donor HLA proteins are presented to recipient T cells by the donor's own antigen presenting cells (APCs) ("direct pathway") or later by migrated recipient APCs to the transplanted lung ("indirect pathway"). APC stimulation induces naive T cells to become memory T cells capable of direct and rapid recognition of alloantigens and subsequent injury.^{66,67}

ACR is defined as the presence of perivascular and/or peribronchiolar lymphocytes in the absence of infectious etiologies. To date, bronchoscopic transbronchial biopsy remains the gold standard for diagnosis of ACR.^{68,69} However, multiple studies have been conducted in assessing less invasive tests such as bronchoscopy-guided airway brushings,⁷⁰ bronchoalveolar lavage (BAL),⁷¹⁻⁷³ or serum biomarkers for diagnosis of ACR.⁷⁴ Similarly, spirometry testing has utility but is not diagnostic.⁷⁵ Thus after several decades of attempts to find a less invasive, more precise, surrogate marker of ACR in lung transplantation, bronchoscopic tissue analysis remains the most reliable diagnostic modality.

Acute rejection can be seen as early as a week after lung transplantation. Although ACR is more often present as a nonspecific decline in spirometry with no significant radiographic changes, it can manifest as a fatal hypoxic respiratory failure with diffuse pulmonary infiltrates in its severe form. This can make the diagnosis and treatment of other ICU complications difficult. ACR presentation can mimic symptoms of pneumonia, and sometimes ACR can be triggered by earlier pneumonia. Therefore, development of new infiltrates after lung transplantation requires diagnostic evaluation using bronchoscopy with BAL and transbronchial biopsy. It is important to mention that ACR is directly responsible for only a small proportion of deaths in lung transplantation recipients. In fact, less than 4% of deaths are attributable to ACR in the first posttransplant month, and, at later time points, this incidence decreases to less than 2%.⁶⁴ Nevertheless, much attention has been paid to the early diagnosis and treatment of ACR as it remains the most significant risk factor for development of CLAD, which is the ultimate cause of mortality from lung transplantation.^{76,77}

The common first-line therapy for ACR is high-dose steroids with intravenous methylprednisolone; doses range from 10 to 15 mg/kg daily for 3 days, followed by a prednisone taper.⁷⁸⁻⁸⁰ The therapeutic plans for persistent or recurrent acute rejection are variable among centers, nevertheless warranting further augmentation of immunosuppression. This can be achieved by a repeat course of pulse steroids, optimization of maintenance immunosuppression,^{78,82} anti-T-cell agents such as polyclonal ATGs, or an anti-CD52 monoclonal antibody (alemtuzumab) in the treatment of severe and refractory ACR.^{80,83}

Antibody-Mediated Rejection

AMR is now a widely accepted complication after lung transplantation.^{80,84,85} AMR is mediated by donor-specific antibodies (DSA), produced by B cells or plasma cells, and upon binding to their cognate

antigen in the transplanted lung, they cause a deleterious effect via complement-dependent⁸⁶ and complement-independent pathways.^{86,87} DSA may be present at the time of transplantation (sensitized recipient) or develop de novo following transplantation.⁸⁸

The presence of DSA prior to transplantation can lead to hyperacute rejection, which is the most severe form of AMR, and occurs within minutes to hours after lung transplantation. The clinical manifestations are the rapid development of diffuse pulmonary infiltrates and hypoxia followed by systemic inflammatory response syndrome including coagulopathy, thrombocytopenia, oliguria, and hemodynamic instability.^{85,89-91} While hyperacute rejection is generally considered to be a fatal complication after lung transplantation, there are a few case reports of survival after enforcing aggressive immunotherapy strategies.⁹²⁻⁹⁴ Therapeutic approach to hyperacute rejection includes various combinations of high-dose steroids, plasmapheresis, cyclophosphamide, high-dose intravenous immunoglobulin, antithymocyte globulin (ATG), and rituximab, an anti-CD20 monoclonal antibody.^{85,89-94}

Aside from the risk for development of hyperacute rejection, the presence of DSA prior to lung transplantation has been associated with ACR, AMR, and CLAD.⁹⁵⁻⁹⁸ Therefore, prevention through the avoidance of the donor with known DSA HLA targets has been common, but it can significantly limit access to a transplant in the sensitized recipients.⁹⁹⁻¹⁰¹ Alternatively, pretransplantation desensitization using a combination of plasmapheresis, ATG, intravenous immunoglobulin (IVIG), and mycophenolate has been reported with equivalent post-transplantation outcomes to unsensitized patients.^{95,102-104} Overall, hyperacute rejection has become rare since the implementation of more sensitive methodologies for screening recipient HLA antibodies before transplantation.

Pretransplant DSA, as well as the de novo development of DSA after lung transplantation, can be asymptomatic (silent) or result in clinical manifestations of antibody-mediated rejection.^{95-97,103} The clinical presentations of ACR and AMR are indistinguishable. Additionally, ACR and AMR can copresent or one can trigger the other form of rejection.^{105,106} Unfortunately, AMR in lung transplantation has remained a diagnostic challenge.^{88,107} The lung transplant recipient presenting with an otherwise unexplained drop in lung function, anti-HLA DSA, a neutrophilic capillaritis, and positive C4d staining on transbronchial biopsy is highly likely to have AMR as the cause for graft dysfunction. In such cases, a diagnosis of “definite AMR” is suggested.^{88,90,107} However, this scenario is uncommon, and the more common clinical presentation is of a patient with an unexplained drop in pulmonary function and a new or increasing titer DSA. In these cases, lung biopsy does not suggest an alternative diagnosis or demonstrate confirmatory features of AMR. Therefore, the absence of confirmatory histology should not automatically rule out the diagnosis of AMR.^{90,107}

In general, there is no consensus agreement about the choice of agent or duration of therapy for AMR. Therapeutic options have been extrapolated from renal transplant and other areas of medicine without clinical trials. Treatment has generally consisted of multiple sequential interventions. It is very common to initiate therapy with pulse steroids (methylprednisolone 0.5-1 g daily for 3-5 days),¹⁰⁸ followed by plasmapheresis and high-dose IVIG.¹⁰⁹⁻¹¹² In recent years, there has been more interest in adding rituximab to the therapeutic regimen in order to deplete mature B cells and decrease the rate of recurrence of AMR.^{112,113} Additionally, a plasma cell-targeted therapy using proteasome inhibitors such as bortezomib has been used

successfully in management of AMR refractory to IVIG, plasmapheresis, and rituximab.¹¹⁴

Chronic Lung Allograft Dysfunction

CLAD is characterized by persistent loss of pulmonary function, which cannot be explained by other potentially reversible complications such as acute rejection, infection, or bronchial stenosis. It affects up to 50% of lung transplant recipients after 5 years and is the major cause of overall morbidity and mortality after lung transplantation.^{7,115,116} CLAD is an umbrella terminology embracing different phenotypes including obstructive CLAD and restrictive CLAD.^{116,117} Obstructive CLAD includes bronchiolitis obliterans syndrome (BOS), which is caused by recurrent inflammation, destruction, and eventual fibrosis of small airways, forming obliterative bronchiolitis (OB) lesions in the lung allograft. It presents as a persistent nonreversible obstructive ventilatory decline in spirometric measures of lung function with an essentially clear chest radiograph. High-resolution CT imaging of the chest often demonstrates air trapping, tree-in-bud opacities, or bronchiectasis. Due to the patchy distribution of OB lesions in lungs, transbronchial biopsy is insufficiently sensitive to achieve diagnosis. Therefore, the diagnosis of BOS is made by at least a 20% decline in FEV₁ from the best postoperative baseline, assessed by two measurements with a minimum interval of 3 weeks.^{116,118,119} BOS is thought to be irreversible; however, recently it became clear that 30% to 40% of patients with a diagnosis of BOS may respond to treatment with azithromycin. A placebo-controlled trial in patients with BOS confirmed that azithromycin was superior to placebo for improvement in FEV₁ in established BOS.^{120,121} Most patients who responded to azithromycin had elevated BAL neutrophilia during diagnosis. This observation led to a further subclassification of obstructive CLAD to BOS and a new phenotype known as *neutrophilic-reversible allograft dysfunction* or *azithromycin-responsive allograft dysfunction*.^{116,118,119}

Approximately 70% of CLAD is attributable to obstructive CLAD, and 30% to the restrictive phenotype of CLAD, also known as *restrictive allograft syndrome* (RAS).¹¹⁷ RAS is characterized by a restrictive pulmonary function decline and persistent parenchymal infiltrates on chest radiography. CT of the chest can demonstrate subpleural thickening and nonspecific interstitial changes. Additionally, organizing pneumonia, pleuroparenchymal fibroelastosis, and obliterative bronchiolitis may be seen in the histopathology.¹²² Unfortunately, the median survival after development of RAS is limited to 6 to 18 months, as opposed to 3 to 5 years in BOS.¹¹⁷

The medical management of CLAD centers around stabilizing rather than restoring graft functions. For management of BOS, current guidelines recommend conversion of cyclosporine to tacrolimus, antireflux surgery (e.g., Nissen fundoplication or Toupet fundoplication) in the case of documented gastroesophageal reflux, and a trial of azithromycin for a minimum duration of 3 months in patients with obstructive CLAD.^{118,119} Currently there are no formal guidelines for management of patients with restrictive CLAD. Some beneficial effects have been reported using pirfenidone and alemtuzumab in RAS.¹¹⁷ While selected cases may consider retransplantation for end-stage BOS, emerging data discourage this in RAS.^{118,119,123} For the majority of patients with end-stage CLAD, palliation becomes the priority. Symptom control in advanced disease remains challenging. Noninvasive ventilation for hypercapnia is generally ineffective, and ventilatory support and subsequent weaning are usually unsuccessful.¹²⁴

KEY POINTS

1. Lung transplantation continues to offer hope for many advanced lung disease processes. Much has been learned about the natural history of these otherwise terminal lung diseases, which has

influenced significant changes in the overall practice of lung transplantation, including the lung allocation system and the donor selection criteria.

KEY POINTS—cont'd

2. Primary graft failure (dysfunction) is a severe form of ischemia-reperfusion injury and carries enormous morbidity and mortality.
3. Lung transplant recipients with postoperative respiratory compromise should be maintained "on the dry side."
4. Growing evidence suggests that suboptimal early immunosuppression, as well as recurrent aspiration from reflux disease, are the two most modifiable risk factors associated with chronic rejection. Patient selection, consideration of antireflux surgery prior to transplantation or early after, and appropriate immunosuppression schedules should be implemented in protocols at every center.
5. Hyperammonemia continues to be a rare but feared complication after lung transplantation, given that its mechanism has yet to be understood. Aggressive management options including gut decontamination, high levels of dialysis, and pharmacologic treatments targeted at urea-cycle enzyme deficiencies are the only available tools but have yet to show promise in changing outcome.

ANNOTATED REFERENCES

Hachem RR, Trulock EP. The new lung allocation system and its impact on waitlist characteristics and post-transplant outcomes. *Semin Thorac Cardiovasc Surg* 2008;20:139–142.

This review clearly explains the current lung allocation process, which basically is geared toward making organs available to those who need them more urgently because of their underlying disease process and its expected outcome. A thorough comparison of the prior allocation process to the current one in terms of waiting time, waiting mortality, and more important, the steady proportional increase of idiopathic pulmonary fibrosis as the underlying cause of transplantation is made. This increase is explained by the comparable uncertainty of the disease's natural history and the high mortality of its exacerbations.

This yearly document published by the International Society of Heart and Lung Transplantation summarizes and explicitly describes the statistical trends of lung and heart-lung transplantation. This

registry allows the reader to put in perspective the indications for transplantation, the donor characteristics, their impact on transplantation outcomes including rejection, complications and survival, as well as the centers offering transplantation and their influence on these outcomes in terms of the case load they are challenged with. It allows an organized chronologic understanding of lung and heart-lung transplantation outcomes.

Christie JD, Sager JS, Kimmel SE, Ahya VN, Gaughan C, Blumenthal NP, et al. Impact of primary graft failure on outcomes following lung transplantation. *Chest* 2005;127:161–165.

This single-center retrospective study conducted by field experts looked into the overall incidence of grade III primary graft failure in 255 consecutive procedures done in a period of over 10 years. It demonstrated an incidence of 11.3%, an increased mortality, worsened hospital length of stay, and increased duration of mechanical ventilation. Some 73.3% of patients who received the diagnosis of primary graft failure died during their hospitalization, versus 14.2% of those who did not. A 1-year follow up also demonstrated significantly affected physical function in those who had experienced primary graft failure.

Liver transplantation has been a successful surgical procedure for over 50 years. The pioneering work done by Thomas Starzl, who performed the first successful human liver transplant in 1967, defined both the surgical approach and efforts in controlling rejection.¹ The 1970s brought about advances in immunosuppression with the introduction of antilymphocyte globulin (ALG) developed at the University of Minnesota.² The early immunosuppressive regimens elevated liver transplantation as a viable surgical option for patients suffering from end-stage liver disease (ESLD). Orthotopic liver transplantation (OLT) is now offered more broadly, with more than 130 liver transplantation centers in the United States.³ Finally, the further advancement of immunosuppressive agents such as tacrolimus and interleukin (IL)-2 receptor blockers has paved the way for improved outcomes and survival. The current 1- and 5-year patient survival rates are 86% to 90% and 72% to 80%, respectively.⁴

Other advances have improved the outcomes of the field of liver transplantation including critical care management, surgical preparation of the graft, increases in preservation time, a smoother surgical procedure, and availability of organs less distant from the donor.^{5,6} Despite these advancements, the rates of liver transplantation have not changed dramatically for nearly 20 years.⁷ There are roughly 11,500 patients currently listed for liver transplantation with about 6000 liver transplantations performed in the United States in 2014.⁴ The majority of these were deceased donor, adult recipients.

■ PREOPERATIVE CONSIDERATIONS

Orthotopic Liver Transplantation Candidate Selection

OLT is the definitive treatment for many disease processes, including cirrhosis (both cholestatic and noncholestatic), biliary atresia, acute hepatic necrosis, metabolic disorders that result in hepatic failure, and malignancies of the liver or biliary tree as well as other rare causes of ESLD and even rarer causes of catastrophic traumatic liver injury.^{3,8,9} The savings of cost, morbidity, and mortality of patients receiving transplantation versus long-term management of severe liver disease makes this a viable option for many patients.

Of particular note is the indication of OLT in patients with hepatocellular carcinoma (HCC). The majority of cases in the United States and Europe are caused by chronic hepatitis C virus (HCV); however, in other parts of the world, hepatitis B virus (HBV) and exposure to aflatoxin B are the leading risk factors. Most develop HCC in the setting of preexisting cirrhosis, making surgical and oncologic treatments challenging.⁹ It is in this setting that OLT has become a standard treatment for patients who have minimal disease burden, and the refined selection criteria for this indication became known as the Milan Criteria. In 2002, researchers at UCLA demonstrated equivalent outcomes with a slight broadening of the Milan criteria.^{6,10} Other criteria, including the Kyoto criteria, have also led to acceptable results.^{11,12} Currently, both the Milan criteria and the UCLA criteria are recognized in the United States; however, expansion of these is likely to occur (Table 159-1).

In 2002, UNOS adopted the Model for End-Stage Liver Disease (MELD) and its pediatric counterpart, Pediatric End-Stage Liver Disease (PELD). The MELD calculation is used for all patients aged 12 and older for the purpose of listing patients for potential transplantation. The components of MELD include bilirubin (mg/dL), serum creatinine (mg/dL) or need for dialysis, and INR. For patients younger than 12, albumin, growth failure, and age at listing are also considered. The MELD score is predictive of mortality within 90 days of transplantation (Fig. 159-1). In 2012, a new policy called Share 35 helped distribute grafts more quickly to patients with a MELD score greater than 35.⁴ From a prognostic standpoint, it is helpful to understand the severity of the patients' ESLD for discussions of ongoing critical care goals.⁹ MELD/PELD scores can be easily calculated via multiple web-based calculators. The Organ Procurement and Transplantation Network (OPTN) website has multiple organ failure allocation calculators available with links to explanations for their use.¹³

Improvements in care over time (i.e., adoption of the Milan Criteria) have resulted in recipients who would previously have died while awaiting transplantation. Recipients are now more complex, older, have preexisting renal failure requiring dialysis (resulting in greater need for combined liver-kidney transplantation), require pretransplant hospitalization, and have longer wait times. For example, there are clear relationships that preoperative obesity and diabetes are related to early post-liver transplant morbidity. Prior to OLT, patients are often precipitously ill secondary to an inciting infection or fulminant hepatic failure. The success of performing transplantation in these patients is due to changes in immunosuppression therapy, surgical technique, and organ selection as well as anesthesia and critical care management in the early postoperative period.¹⁴⁻¹⁷ In addition to the Milan criteria, the stratification of recipients based on MELD scores have exception points given for portopulmonary syndrome to define those who will have the most successful posttransplant course.^{18,19} There is currently debate about whether these criteria are too broad as some patients have a much higher than expected survival while others perish while awaiting transplantation.^{18,20}

Donor Selection

In the past two decades, there has been a logarithmic increase in the demand for organs without a similar increase in donors. The concept of brain death, refined in the late 1960s, greatly expanded the donor pool. The concept of extended criteria donor (ECD) has emerged, making organs available for transplantation to those who would have otherwise died while on the waitlist.²¹⁻²⁵ Some of these characteristics include prolonged cold ischemia time (>12 h), HBV- or HCV-positive donors for HCV-positive recipients, elderly, nonhepatic solid cancers, severe electrolyte derangements, and evidence of parenchymal injury.²⁵⁻²⁸ This donor pool also includes patients with longer donor hospitalizations, donation after circulatory death (DCD), partial or segmented grafts (deceased and living), and even patients on extracorporeal membrane oxygenation.²⁹ This has led to organs procured from individuals who would not have been previously considered to be appropriate donors and transplantations to those who would not have otherwise received an organ at that time.³⁰⁻³² This is

| MELD score | Mortality at 3mo |
|------------|------------------|
| <9 | 1.9 |
| 10–19 | 6 |
| 20–29 | 19.6 |
| 30–39 | 52.6 |
| >40 | 71.3 |

FIGURE 159-1 ■ Model for end stage liver calculations. (From Wiesner R, Edwards E, Freeman R, et al. Model for end-stage liver disease (MELD) and allocation of donor livers. *Gastroenterology* 2003;124:94. Fig. 2.)

TABLE 159-1

Liver Transplantation Criteria for Hepatocellular Carcinoma

| | MILAN | ULCA | KYOTO |
|------------------------------|---------------------|-----------------------|----------------|
| Single tumor | <5 cm | <6.5 cm | |
| # Tumors (each cm) | 3 tumors, 3 cm each | 3 tumors, 4.5 cm each | <10, 5 cm each |
| Total tumor size | | 8 cm | DCP <400 |
| 5-year survival | 75% | 52% | 82% |
| Disease-free 5-year survival | 83% | 79% | 93% |

conceptualized in the donor risk index, which is a method of predicting graft failure to help determine suitability of the organ to a recipient match.

There are many reports that support the use of ECD organs due to the fact that recipients are less ill at the time of transplantation and can have a more stable postoperative course. The average MELD scores are lower prior to transplantation, and the survival outcomes are equivalent, with most deaths attributable to the recipient age or other comorbidities rather than primary graft dysfunction.³³ Even hepatic lobar transplantation has been used in adults, although the reduced functional tissue mass has often resulted in delayed or inadequate liver function.³⁴ Last, another higher risk ECD transplant situation is what has been termed the *domino OLT*. In these cases, patients with ESLD secondary to familial or metabolic liver disease become both the donor and recipient in the same operation. Their somewhat diseased liver will then become the allograft into an otherwise nontransplantable host. The idea is that the second patient may have enough remaining graft function to allow for a more suitable donor to be identified.^{35,36} The intensivist should recognize that patients receiving ECD livers are at a higher risk of immediate graft malfunction or complications related to their comorbid state as compared to recipients of brain dead organs.

Recipient Operation

The more intricate details of liver transplant operation are beyond the scope of this chapter; however, a few salient points are worth mentioning as they can directly impact the immediate postoperative course. It cannot be stressed enough that any surgical procedure performed on a patient with long-standing portal hypertension is all the more difficult secondary to the vast venous collaterals that often lead to significant blood loss.³⁷ This is in addition to the blood that will be lost

during the usual course of the operation. Other factors, including cold and warm ischemia time, which may affect the quality of the graft; high-volume operative blood transfusion requirements; and reperfusion syndromes, make these patients challenging from a fluid, electrolyte, and organ function standpoint.^{38–41}

As with all types of OLTs, vascular anastomoses can prove troublesome. In cases of partial liver allografts, where there may be vessel size discrepancy or anomalous anatomy, vascular grafts may be used. Most often, this is an arterial graft (taken from the donor at the time of the procurement) and is used as a “jump” graft.^{42,43} Likewise, venous anastomoses can also be difficult but are most often performed primarily and, in rare cases, may also include a vascular graft to ensure adequate flow into the graft.

There are two main approaches to the anastomoses for biliary drainage of the liver graft: choledochocholedochostomy (duct-to-duct) and Roux-en-Y choledochojejunostomy. The duct-to-duct anastomosis may be done over a T-tube to assist in stenting the anastomosis and allowing for external monitoring of the graft. Many early biliary complications have been associated with T-tube use.^{44,45} The benefit of this approach is that postoperative ERCP can still be utilized for ductal evaluation and stent placement if needed (Fig. 159-2).

ACUTE POSTOPERATIVE MANAGEMENT

Respiratory Support

Postoperative respiratory disorders are commonplace following OLT, and many risk factors for post-OLT pulmonary complications have been identified.⁴⁶ Separate from portopulmonary hypertension (PPHTN) is hepatopulmonary syndrome (HPS), which is the hypoxia attributable to ventilation/perfusion (VQ) mismatch, intrapulmonary shunts, and capillary vasodilation with oxygen diffusion limitations secondary to portal hypertension. Liver transplantation effectively and rapidly reverses this dysfunction with graft function unless there are confounding comorbidities. Advanced ventilator maneuvers may be required, including the use of inhaled prostaglandins (Flolan) and inverse ratio ventilation.^{47,48} Ventilator wean failure requiring tracheostomy is unusual in OLT patients. Details of usual ventilation settings, approaches to mechanical ventilation wean, and extubation are described in Chapters 61 and 63. Inability to liberate from mechanical ventilation is predictive of graft failure and mortality at 1 year (Table 159-2).⁴⁹

Coagulopathy and Thrombocytopenia

Most liver transplant patients undergo surgery in the setting of ESLD and are coagulopathic at the time of surgery.^{50,51} The assumption that

ESLD patients are hypocoagulable secondary to the loss of synthetic function of the liver is an incomplete understanding of the pathophysiologic process. It has been demonstrated that the complex balance between procoagulant forces and anticoagulant forces become rebalanced. The synthetic production of our innate anticoagulants is also depressed. Although it may seem counterintuitive, it is for this reason that frequent catastrophic spontaneous hemorrhage is not common.⁵² It is well recognized that these patients lack the usual reserves to maintain normal hemostasis, and they remain at risk for both bleeding diatheses and thrombotic events.

Technical and anesthetic advances have made minimal-transfusion liver transplantation a reality. That being said, there are many operative difficulties that can be encountered that result in massive blood loss to further derange homeostasis. It is important, then, to replace the blood that is being lost as a result of the operation and to correct coagulation using fresh frozen plasma (FFP) and cryoprecipitate to maintain normal fibrinogen levels. This results in fewer blood product transfusions, improved patient outcomes, and reduced costs.

Likewise, thrombocytopenia is common in OLT. In chronic liver disease, the only upregulation of procoagulant factors are of factor VIII and Von Willebrand factor.²⁸ The greatly reduced platelet number is thought to be secondary to multiple factors, including sequestration by the spleen resulting in hypersplenism, increased consumption,

bone marrow suppression, and reduced thrombopoietin levels. Despite the detrimental experimental evidence of platelet transfusion, most centers will transfuse OLT patients to keep the platelet counts greater than 20 K/dL or greater than 100 K/dL in uncontrolled nonsurgical bleeding.

Due to the inconclusive evidence that all blood product transfusions in OLT are more harmful than beneficial, the current literature supports consideration of the targeted use of blood products. Additional steps toward hemostasis using prohemostatic drugs such as aprotinin, lysine analogs, or prothrombin concentrates are warranted.⁵³

Immunosuppression

The advances in immunosuppression used in liver transplantation have dramatically improved the long-term quality of life and survival of patients. There are a few basic categories of commonly used drugs that we will discuss with the understanding that there are no global standardized regimens; the general approaches to these medications, however, are similar. Common regimens used for immunosuppression in OLT may include a combination of corticosteroids, azathioprine (AZT), mycophenolate mofetil (MMF), sirolimus, cyclosporine, tacrolimus, and antilymphocyte antibodies.

Corticosteroids enact their effect by suppressing antibody and complement binding resulting in a reduced synthesis of immunomodulatory cytokines. Steroids also inhibit secretion of IL-1 by macrophages required for antigen presentation and initiation of an acute allograft rejection.⁵⁴ Four corticosteroids are used most often in liver transplantation: hydrocortisone, prednisone, prednisolone, and methylprednisolone. Methylprednisolone is only available in intravenous (IV) formulation and requires hydrolyzation of a succinate moiety for biological activity, thereby requiring some liver function for biological activity. In addition, several biologically active metabolites are produced that prolong the half-life, making this drug unpredictable in liver transplant patients. All corticosteroids become metabolically inactivated by the cytochrome P450 system. Both prednisone and prednisolone are active drugs that do not require activation by the liver

and, therefore, have equivalent bioavailability in both oral and IV routes. Therefore, in the days following liver transplantation, the graft, having been crippled by warm and cold ischemia time, cannot inactivate steroids effectively. Clinically, this liver dysfunction allows for lower doses of steroid to be used with immunologic effectiveness.⁵⁵

MMF, also known by the trade name CellCept, is an ester derivative of mycophenolic acid (MPA) produced by *Penicillium* species. MMF is metabolized by the liver into MPA and inhibits cellular proliferation. It is relatively selective and renders lymphocytes unable to proliferate. MMF also has antiviral effects with activity against HCV and has been found to reduce the recurrence of HCV in patients transplanted for this disease.⁵⁶ Common side effects are gastrointestinal and hematologic, including gastritis, nausea, vomiting, and varying degrees of pancytopenia. Reduction of the dose usually results in resolution of the symptoms without having to completely withdraw the medication.

Cyclosporine and tacrolimus are calcineurin inhibitors. They suppress the immune system by preventing IL-2 production by T cells. Cyclosporine inhibits not only IL-2 but also T and B cell proliferation and differentiation.⁵⁴ Tacrolimus also inhibits the formation of IL-2 but is 100 times more potent than cyclosporine.⁵⁵ Both drugs are metabolized through the cytochrome P450 system.

The adverse effects of the calcineurin inhibitors are primarily nephrotoxicity and, in the case of tacrolimus, neurotoxicity. Renal dysfunction ranges from minimal to irreversible vasculopathic damage. Cyclosporine is also known to promote hypertrichosis and gingival hyperplasia. Tacrolimus, by contrast, has the potential for severe neurotoxicity that warrants immediate withdrawal of the medication. The half-life of cyclosporine is significantly prolonged when given in conjunction with tacrolimus, and thus this combination should be avoided.

Fluids and Electrolytes

The majority of patients undergoing OLT will have a significant positive total body fluid balance. This is due primarily to preoperative conditions that result in fluid accumulation, most notably the state of hyperaldosteronism.⁵⁷ This is aggravated by intraoperative fluid administration. A perioperative pulmonary artery (PA) catheter can determine intravascular volume as well as other hemodynamic parameters. Other methods of volume estimation are serial ultrasound examinations of IVC, RA and PA filling estimations, and noninvasive cardiac output monitoring devices such as FloTrac.

Not only do these patients have increased total body water and sodium levels, but they are also likely to have some degree of renal dysfunction. Dialysis-dependent recipients require judicious use of fluid resuscitation. The amount of volume that the patient receives intraoperatively is dependent upon the details of the surgical case. However, if large volumes of crystalloid or blood were required, these patients will often require early renal replacement therapy (RRT) to help manage the metabolic derangements as well as the fluid balance.^{58,59}

Protocolized fluid administration that focuses on hemodynamic goals has been shown to significantly reduce the volume of crystalloid required and the number of transfusions. These patients benefit from shorter number of ventilator days and reduced number of respiratory complications.^{15,57} In addition, there is a shorter return to antegrade bowel function and no suggestion of increased graft complications. While there is some critical care literature suggesting that a slight positive fluid balance may be beneficial in the general postoperative abdominal surgical patient, it appears that maintaining euvoolemia in OLT is beneficial.

Many patients with long-standing liver dysfunction prior to transplantation develop hyponatremia, which is corrected pre-, intra-, and postoperatively. The danger in rapid sodium correction is central pontine myelinolysis (CPM). Rapid correction may occur occultly and unintentionally via the unaccounted for sodium load in many IV medications, including sodium bicarbonate, albumin, and crystalloids, as well as the use of diuretics, blood products, or aggressive correction of hyperglycemia. Larger changes in sodium concentration have been

associated with prolonged intubation and neurologic complications in several patient populations including liver transplant recipients.⁶⁰

The most common electrolyte abnormalities in the posttransplant liver patient are hyponatremia and hypokalemia. These may persist from preoperative deficiencies and are due to a dilutional effect of the total body concentrations. Hypokalemia is induced intraoperatively to minimize cardiac event risk with the anticipation of labile potassium levels during revascularization of the graft. This is corrected by slow diuresis and judicious replacement with careful avoidance of sodium overload.

Hyperkalemia is a more serious problem and may signal primary graft dysfunction, hepatic necrosis, renal tubular necrosis, or drug toxicity. The usual treatment of hyperkalemia should be employed, including calcium, insulin, glucose, potassium-binding resins, systemic alkalization, and, in severe cases, emergent hemodialysis. Further evaluation as to the cause of the elevated potassium should follow to avoid missing the opportunity to intervene.

Nutritional Support

Resting energy expenditure (REE) of ESLD patients is much higher than one might anticipate.⁵² It is, indeed, a very catabolic state with an average requirement of 30 kcal/kg/day. Preoperatively, most of these patients are clinically malnourished.⁶¹ This can be determined both clinically and through laboratory testing, although assessment of the nutritional status of patients with ESLD can be problematic.⁶² Evaluation of the general muscle mass including the thenar prominence and the robustness of the temporalis muscle can give one a gross estimate of the patient's preoperative nutritional status. More sophisticated and accurate methods of determining the metabolic state of the OLT patient include the measurement from a metabolic cart.

The best predictor of postoperative malnutrition is the underlying cause and progression of ESLD; the more prolonged the course, the more nutritionally deplete these patients will be. Those patients that have a chronic disease leading to liver failure are likely to be in a more precarious nutritional state than the patient who developed acute fulminant hepatic failure from a drug overdose, for example.⁶³ What is clear is that the average liver transplant patient is likely to be nutritionally deplete, and careful attention to nutrition is imperative for success of the graft and the patient's recovery.

After transplantation, the best determinant of metabolic stress and ongoing nutritional needs is the allograft function.⁶⁴ In patients who have excellent early allograft function, nutritional goals are likely to be met with enteral diets, which is the preferred method for nutrition of the critically ill patient when possible. There are many benefits to enteral feeding for the liver transplant patient, including maintenance of the enterocyte mass and higher rates of visceral protein synthesis. Another benefit to enteral nutrition is the added avoidance of total parenteral nutrition (TPN)-induced cholestasis.⁶⁴ Not only can this be detrimental to the overall graft recovery, but it can also lead to confusion in the interpretation of the liver function tests. Patients who have difficulty tolerating enteral diets are often those who have delayed graft function, have received larger volumes of crystalloid and/or blood products, and are volume overloaded with concurrent bowel edema and ileus. These patients must be managed with parenteral nutrition. A more detailed description of nutritional support is found in a previous chapter.

SPECIFIC CONSIDERATIONS OF THE LIVER TRANSPLANT PATIENT

Operative Complications

Specific complications that arise from the surgical approach that would affect the postoperative course include portal vein thrombosis, hepatic artery thrombosis, and bile leaks. Complications following OLT are low but can be devastating. A summary report from UCLA demonstrated that early primary graft failure, hepatic artery

thrombosis, and portal vein thrombosis rates range from 0.7% to 6% for the adult populations.¹⁰ In their experience, they estimate that nearly 30% of OLT patients had complications that require reoperation. The most common cause of reoperation is bleeding. There are several risk factors identified for reoperation: higher MELD score, pretransplantation hospitalization, mechanical ventilation, vasopressor use, renal replacement therapy, longer ischemia times (both warm and cold ischemia), and more intraoperative transfusions.^{7,15,48,52} Later complications that should make one concerned about vascular compromise or rejection include biliary strictures, new-onset peritonitis, hepatic artery thrombosis, and cholangitis.^{44,45}

Thrombotic Events/Anastomotic Patency

Transplant surgical teams monitor the vascular anastomoses involved in liver transplantation in various ways. One approach is to leave an internal Doppler probe at the anastomosis and monitor the auditory wave output for bi- or triphasic flow. Another approach is to do diagnostic duplex ultrasound of the hepatic artery (HA) and portal vein (PV) within the early postoperative period.⁶⁵ The first method is more invasive and carries a small risk of increased infection, potential for anastomotic injury, inability to reposition the probe were it to become dislodged, as well as discomfort upon removal. Although bedside duplex of the graft and its anastomoses is noninvasive, it can be limited by bowel gas and is fairly uncomfortable in the immediate postoperative period unless the patient remains intubated and sedated.⁶⁶ In addition, it is not real-time monitoring and, unless previously scheduled, will be performed in a reactionary manner in response to metabolic or physiologic derangements. The use of one technique over the other is determined by the experience of the surgeon and the regional practices (Table 159-3).

Biliary Complications

Strictures, leaks, and biliary stones cause a significant morbidity for 30% to 50% of liver transplant recipients (higher in DCD OLT). The two most common reconstruction types are to either perform a duct-to-duct anastomosis (choledochocholedochostomy with or without T-tube) or a choledochojejunostomy (Fig. 159-3).⁶⁵ In the early postoperative period, bile leaks are the most common biliary complication. These are often difficult to detect, as they may be fairly asymptomatic, with only mild elevations of transaminases and bilirubin. The cause of the leak is often of more concern than the leak

itself; leaks can be caused by pure technical errors in the anastomosis, devascularization of the ductal tissue, or hepatic artery thrombosis.^{65,67} Further investigation is warranted. Dealing with biliary complications is often dependent upon the expertise and experience at each transplant center and may include ultrasound, angiography, cholangiography, MRCP, ERCP, and percutaneous drainage.⁶⁸ It is imperative to maintain a heightened awareness and close monitoring for these complications with aggressive treatment if detected to alleviate long-term sequelae and graft damage.

FIGURE 159-3 ■ Post-OLT biliary complications timeline.

■ ORGAN PHYSIOLOGY

Posttransplant Cardiomyopathy

ESLD patients often have preoperative hemodynamic abnormalities (e.g., hyperdynamic, hypotensive, vasodilated) resulting in high cardiac output, low systolic blood pressure, and low systemic vascular resistance.⁶⁹ This cirrhotic cardiomyopathy is thought to be secondary to the multiple arteriovenous communications, activation of the renin-angiotensin-aldosterone and sympathetic nervous system resulting in vasodilation, reduced circulatory blood volume, and sodium and water retention. The persistence of this hyperdynamic circulation is unpredictable but has been reported to take up to 2 years after successful liver transplantation for resolution.⁴⁶

Rarely, the OLT patient will develop overt cardiac failure after liver transplantation. Identification of the specific risk factors has not been successful. It is thought that elevated BNP and PA pressures in the early postoperative period may be a predictor.^{70,71} It is clear that the postoperative hemodynamic instability is worsened by anemia, PHTN, PPHTN, and cardiovascular disease. In the immediate postoperative period, the relative volume deficit of these patients is preferentially managed by resuscitation with colloids including albumin and blood products. Intravascular volume resuscitation using blood products with vasoconstrictors is used to maintain adequate perfusion for the new graft. This is done in an attempt to balance the additional morbidity of large volume with potential visceral ischemia.

Pulmonary

PPHTN is a long-standing fibroproliferative disorder of the pulmonary arteries that will result in pulmonary hypertension, hypoxia, dyspnea, and eventually right heart failure. This process is brought on by severe portal hypertension.¹⁶ Because of the insidious nature of the development of this disorder, it is an equally slow process to reverse once liver transplantation has been performed. However, liver transplantation is the definitive treatment for this disease process. Because 8% to 20% of OLT patients present with some degree of pulmonary hypertension, additional use of pulmonary artery vasodilators may be warranted, not only for pulmonary function but for reduced hepatic congestion as well.¹⁹ In these patients, it is not uncommon to employ additional hemodynamic monitoring devices to estimate pulmonary artery pressure and cardiac output. In cases of severe preoperative PPHTN, there is an increased risk of graft failure due to liver venous congestion and right heart failure; if severe or long-standing, these changes can become fixed and result in increased postoperative mortality.²⁰ It becomes important to manage these patients with perioperative pulmonary artery pressure and right heart pressure monitoring, most commonly accomplished by a PA catheter. However, this can also be supplemented with an indwelling miniaturized transesophageal echocardiography (mTEE) probe in centers that have a vast experience with these devices.⁷⁰

Renal

Hepatorenal syndrome (HRS) is the decline of renal function with a measured rise in creatinine to greater than 2.5 mg/dL and double the patient's preillness baseline.⁷² The onset may be insidious, as the urine output may remain relatively unchanged and may, therefore, go unnoticed. The etiology of HRS is due to the hemodynamic dysfunction associated with ESLD as described for PPHTN. Remarkably, however, the renal morphology is typically normal in this disease state. The long-standing renal dysfunction can result in permanent damage to the renal parenchyma. We will not discuss the combined liver-kidney transplant patient in any depth other than to recognize that prolonged renal failure prior to OLT is a marker for ongoing renal dysfunction and may, therefore, necessitate co-transplantation.

In the postoperative period, acute kidney injury is common and can occur in up to 60% of patients. There are suggested negative rela-

tionships between the use of prolonged vasoactive drugs, hypotension, higher MELD scores, and blood product administration with decreased renal function. Renal replacement therapy (RRT) is required in nearly 10% of these patients with a doubling of their mortality rate at 1 year.

Central Nervous System

Neurologic complications are common and can affect 30% to 60% of all solid organ transplant patients, including 15% to 30% of OLT recipients.⁷³ It has also been found that postoperative confusion is more common in OLT patients whose indication for transplant was alcoholic liver disease as compared to other causes of ESLD. Patients with minimal pretransplant encephalopathy, an uncomplicated surgical course, and adequate graft function should recover from anesthesia quickly. Any delay or decline in mental status warrants a thorough evaluation of other causes.

Similar to other solid organ transplant recipients, major complications include alterations in consciousness, seizures, cerebrovascular events, and CPM. The majority of these complications are secondary to opportunistic infections, drug toxicities, and metabolic changes. Although the preferred imaging modality is MRI, previous studies suggest that CT scan is utilized most often. The awareness that structural abnormalities play a much smaller role in postoperative mental status changes should direct a heavier use of MRI as the diagnostic imaging modality of choice.

Two of the most serious causes of coma in OLT are osmotic demyelination syndrome (ODS) and posterior reversible encephalopathy syndrome (PRES).⁷⁴ ODS includes the diagnosis of both central pontine (CPM) and extrapontine demyelination (ECM) processes. Differentiating PRES from ODS can be very difficult and cause significant diagnostic confusion. A closer evaluation as to the specific causes of each may help differentiate the etiology of the mental status change.

Hinchey et al. first described PRES in 1996 as vasogenic edema in the posterior circulation regions of the brain with the resulting altered consciousness, visual disturbances including cortical blindness, and eventual coma.⁷⁵ Classically, this process is completely reversible. It has been typically associated with hypertensive episodes but has also been described in patients with severe electrolyte abnormalities. In the postoperative liver transplant patient, it has also been associated with calcineurin-inhibitor and sirolimus toxicity.⁷⁶ Cessation or reduction in calcineurin dose can have dramatic improvement with the co-administration of ongoing supportive care including antiepileptics.⁷⁷ There is no other specific treatment to date.

CPM, on the other hand, is a neuropathologic process of osmotic demyelination secondary to correction of hyponatremia, first described in 1959.⁷⁶ Classically, it is presented as a tetraplegic, malnourished liver failure patient or postoperative OLT patient. The definition has evolved to include other causes of severe metabolic and electrolyte derangements including septic shock, burns, and HIV. Because liver transplantation is frequently burdened by osmotic and electrolyte imbalances, ODS deserves diligent attention. Distinction between PRES from CPM may be performed with diffusion-weighted imaging MRI and, specifically, the presence of increased T2 signaling in the posterior white matter. However, unless there is acute cytotoxic edema associated with PRES, the radiographic findings of delayed-diagnosis PRES and active ODS may look very similar. Aggressive replacement or reduction in the calcineurin inhibitor must be undertaken as well as judicious fluid management and nutritional support.

Calcineurin inhibitors, cyclosporine, and tacrolimus are commonly used in liver transplantation immunosuppression regimens. Their toxic effects have been associated with multiple neurologic complications that can manifest at any time during the posttransplant course. In the early postoperative period, calcineurin inhibitors are often used in higher "induction" doses resulting in dose-dependent neurotoxicity.^{78,79} The manifestation of these effects is typically tremors, headaches, and encephalopathy, and, in severe cases, PRES can develop. Reduction of these neurotoxic immunosuppressants or replacing them with less toxic medications will often resolve the clinical manifestations.

Critical illness weakness may affect up to 7% of liver transplant recipients.⁷⁷ It is characterized by symmetric weakness in the limbs preferentially affecting the more proximal muscles; it can even involve the respiratory muscles as described by Osler in 1915. One can distinguish between the critical illness myopathy (CIM, which is a primary myopathy secondary to loss of myosin heavy chains) from critical illness polyneuropathy (CIP) by means of a simple sensory examination. However, because OLT patients are often sedated or have other reasons for altered mentation, this can prove to be difficult. Advanced electrophysiologic testing is likely to be required with a concomitant neurology consultation. If these studies prove to be equivocal or normal, a muscle biopsy may be required. CIM is more common and is associated with higher rates of recovery. A primary risk factor for development of critical illness myopathy is the catabolic nature of the post-liver transplant state with subsequent skeletal muscle wasting.⁷⁷

CIP, on the other hand, is speculated to be secondary to derangements in microcirculation resulting in neuronal injury and axonal degeneration. Hyperglycemia can exacerbate the problem. Diligent glucose control can reduce the rates of critical illness polyneuropathy and reduce ventilator days.^{78,79} Other risk factors include a higher illness severity, requirement for hemodialysis, and higher doses of steroid use in the postoperative period. It is important to understand that both of these conditions can coexist as the risk factors overlap significantly (Tables 159-4 and 159-5).

Alterations in consciousness, such as encephalopathy, may carry over from the patient's pretransplant condition.⁷⁹ A protracted pretransplant course of encephalopathy portends a much higher risk of posttransplant neurologic complications. With either delayed allograft function or primary allograft failure, hepatic encephalopathy can precipitously appear. In addition, liver dysfunction will alter the pharmacokinetics of many medications, worsening the clinical picture. Many causes of ESLD can directly affect the nervous system (e.g., Wilson's disease, primary biliary cirrhosis, and amyloidosis). With recovering allograft function, these neurologic manifestations will often improve and occasionally completely resolve. To minimize the risk of medication-induced confusion, avoidance of benzodiazepines,

narcotics with active metabolites, and medications that require hepatic metabolism or clearance should be undertaken.⁷⁸ A more thorough review of delirium can be found in a previous chapter, understanding that in the OLT population, akinetic delirium is more common.⁸⁰

Early Infectious Complications

Evidence of sepsis should invoke a workup of the patient for infectious causes common to all ICU patients, including pneumonia, urosepsis, and line infections.⁸¹ The most common cause of in-hospital death of liver transplant patients is infection. Nearly 80% of solid organ transplant patients will develop infections, mostly from bacteria, and the overall infection rate within the first 30 days remains at about 25%.⁸² There are many factors that increase the risk of bacterial infections following OLT, including ischemia-reperfusion injury of the graft, large-volume blood transfusions, and causes of cholangitis including hepatic artery thrombosis and biliary strictures.⁸³ This discussion will not include information found in previous chapters regarding sepsis, pneumonia, and the need for adequate nutrition.

Because immunosuppression is necessary to allow for symbiosis of the graft, patients must be protected prophylactically against opportunistic infections.^{55,82} Liver transplant patients are given trimethoprim-sulfa prophylactically for life to protect against *Pneumocystis jirovecii*. Occurrences of *P. jirovecii* are now usually only found during times of withdrawal of prophylaxis and are treated with resumption of trimethoprim-sulfa. As with all opportunistic infections following OLT, reductions in immunosuppression may be required.

There are specific issues that pertain to liver transplant patients that may be different from those of other critically ill ICU patients. The liver transplant patient is susceptible to recurrence of the inciting hepatitis virus that resulted in liver failure or HCC.^{2,84} They are also at risk of other viral infections that would be uncommon in the general ICU population such as CMV and EBV that may occur as a result of induction immunosuppression therapy. These comprise nearly 20% of infections and can also include Epstein-Barr virus (EBV), cytomegalovirus (CMV), and recurrent hepatitis B (HBV) or hepatitis C virus (HCV).

CMV is a member of the human herpesvirus group. Infection by CMV is defined as detection of viral proteins in any body fluid or tissue specimen, fever greater than 38°C for 2 to 4 days, and neutropenia or thrombocytopenia.⁸⁵ When CMV infects and causes end organ disease, this can be particularly devastating in an immunosuppressed and metabolically stressed liver transplantation host. Two common CMV infection syndromes are hepatitis and pneumonia. When the lungs are affected by CMV infection, the ensuing pneumonia is often superinfected with bacteria, resulting in one of the most life-threatening complications of immunosuppression. Other noninfectious consequences of CMV include an increased risk of allograft rejection, invasive fungal or bacterial infections, and even activation or acceleration of other viruses such as HCV and EBV. It is noteworthy that even "successful" antiviral treatment may still result in persistence of CMV within hepatocytes and biliary epithelium rendering the patient with a lifetime risk of reactivation, chronic inflammation, and rejection.⁸⁶

The risk of acquiring CMV infection or disease is determined by the pretransplant serologic status of both the donor and the recipient, with the highest risk assigned to the seronegative recipient of an organ from a seropositive donor.⁸⁵ Most of these recipients will seroconvert, and most will eventually develop symptoms. Even those that are seropositive prior to transplantation can become superinfected with donor CMV from the allograft. Other risk factors include specific immunosuppressive medications including prednisone, calcineurin inhibitors, and thymoglobulin.⁸⁷

Prevention and treatment of CMV begins at the time of induction immunosuppression with administration of antiviral agents prophylactically. Prophylactic antiviral therapy does not protect the patient from primary infection with CMV, but it delays the onset of viral replication. Primary CMV infections are often observed upon cessation of prophylactic antivirals.^{83,86} Patients are then monitored carefully for any signs of infection, tested immediately with PCR, and antiviral

CMAP, compound muscle action potential; SNAP, sensory nerve action potential.

therapy initiated immediately upon detection. There is no specific threshold value for seropositive recipients, and treatment is determined based on the clinical suspicion. Any instance of CMV DNA detection warrants immediate treatment with antiviral medications. When CMV disease occurs, valgancyclovir is the most effective therapy.

Acute EBV infection presents with fever, malaise, leukopenia, lymphocytosis, and thrombocytopenia. Nearly 90% of adults are EBV seropositive, but most occur as subclinical infections.⁸² It is presumed that in the liver transplant patient, EBV infections are a result of reactivation rather than primary infection. Other risk factors for EBV infection in liver transplant patients are CMV donor-recipient mismatch, CMV disease, and high-dose immunosuppression.⁸³ There is an association between EBV and posttransplant lymphoproliferative disease (PTLD). However, it is relatively uncommon in adult liver transplantations. EBV viremia by PCR is not diagnostic of EBV PTLD. The initial treatment for PTLD is reduction of immunosuppression. Escalation to rituximab and cytotoxic chemotherapy is done only if a clinical response fails to occur within 2 to 4 weeks of withholding immunosuppression.

Hepatitis B core antibody (HBcAb)-positive and hepatitis B surface antigen (HBsAg)-negative donors are routinely utilized throughout the world. Careful prophylaxis with hepatitis B immunoglobulin (HBIG) and an antiviral at the time of transplantation has resulted in a reduced incidence of HBV infection even with HBcAb-positive grafts.⁸⁸ Some centers are using potent antivirals without HBIG with success in selected patients. Unrecognized reactivation of HBV can lead to graft failure and recipient death.

Hepatitis C virus-related liver disease has become one of the world's leading OLT indications.⁸⁹ It is well known that if HCV RNA is present at the time of OLT, not only does it persist, but also it can result in a chronic active hepatitis in up to 60% of patients. A smaller proportion of patients will experience an aggressive decline with fulminant fibrosing hepatitis and an accelerated development of cirrhosis. For these few patients, early retransplantation is their only option for survival. Identified risk factors for HCV recurrence after OLT include co-infection with HBV, rejection therapy, female recipient, recipient age greater than or equal to 50 years, ECD, and no HCV antiviral treatment.^{14,90} There does not appear to be any difference in the recurrence rate with different induction therapies.⁵⁵ Ideally, eradication of HCV takes place prior to transplantation; however, the treatment cannot be tolerated by all recipients. It is estimated that approximately 20% of patients achieve long-term viral clearance after OLT with completed therapy.⁹⁰ After OLT, recurrence can be treated with peginterferon, ribavirin, and HCV protease inhibitors. HCV protease inhibitors can lead to extreme elevations of tacrolimus and cyclosporine.

Aspergillus infections will affect 1% to 3% of liver transplant patients.⁹¹ These infections occur early in the posttransplant period with a median time of onset post transplantation of 16 to 17 days, although *Candida* infections are more common. Invasive fungal infections used to be a fatal consequence of extreme immunosuppression.^{81,92} Modern, more targeted immunosuppression regimens and better tolerated antifungal therapy have resulted in fewer *Aspergillus* infections and better recovery. Common prophylaxis agents include triazole antifungals (itraconazole, voriconazole, posaconazole), polyene antifungals (amphotericin B products), or echinocandins (caspofungin, anidulafungin, micafungin). Caution must be used with these drugs as they can alter the levels of the immunosuppression drugs as well as interact with the P450 enzyme system. Common antiviral drugs will also induce drug clearance and lower the effective dose of antifungals.

PRIMARY GRAFT DYSFUNCTION AND RETRANSPLANTATION

Primary graft dysfunction (PGD) leading to graft failure is a rare but devastating occurrence and is the leading cause of retransplantation in

TABLE 159-6

| Need for transplant 15-180 days from primary transplant |

liver recipients.⁹³ PGD is the inadequate metabolic function of the liver graft at any point following liver transplantation. There are many risk factors for PGD, including higher risk donors, increased need for blood transfusion, and perioperative vasopressor requirement (which may be a surrogate for tissue bed hypoperfusion). The etiology of PGD and subsequent graft failure is thought to be due partially to the development of ischemic cholangiopathy, which is 10 times higher in DCD as compared to brain death donation. Other studies report marked cellular energy depletion with the increased warm and cold ischemia time as experienced in circulatory death.

Although the exact mechanisms are complex and multifactorial, it is clear that early graft dysfunction in the early posttransplant period is negatively predictive of both graft and patient survival.^{50,67,68} Clinical symptoms of PGD or failure are altered mental status, failure to awake from anesthesia, clearance of bilirubin, and ongoing hyperdynamic cardiovascular physiology. Several diagnostic criteria have been proposed for identification of primary graft dysfunction at 7 days after transplantation including INR greater than 1.6, bilirubin greater than 10 mg/dL, and ALT or AST greater than 2000 IU/L.⁹⁴

Up to 23% of liver allografts are predicted to fail over the lifetime of the recipient, and up to 19% of patients who experience early graft failure will go on to retransplantation.⁹⁵ During the first 7 days following primary transplantation, the risks of primary graft failure (PGF) are prolonged warm and cold ischemia time, ongoing life support, early variceal bleeding, and younger recipient age.⁹⁶ It is thought that younger patients are more likely to have a more robust immune response resulting in early aggressive graft damage as has been found in other solid organ studies. PGF is the leading cause of retransplantation within the first week (>40%) followed by hepatic artery thrombosis (approximately 25%).⁹⁷ Interestingly, the cause for graft failure at 1 month is reversed secondary to the potential for collateral perfusion with progressive loss of the hepatic artery (Table 159-6).^{98,99}

CONCLUSION

The postoperative care of the liver transplant recipient patient is complicated by the slow resolution of the derangements of ESLD: hyperdynamic, vasodilated, hyperaldosteronism with PPHTN, PHTN, and renal dysfunction. These patients can be some of the most physiologically challenging to manage. They are also at risk for early, invasive infections and reinfection with hepatitis viruses. Rarely, they can develop complications or infections resulting in fulminant hepatic failure and will require retransplantation. However, when successful, the long-term benefits of transplantation make this endeavor rewarding.

KEY POINTS

1. Transplant recipients with cirrhotic ESLD will exhibit postoperative hemodynamics similar to their preoperative state. They may require medications to lower their pulmonary artery pressures for weeks in order to prevent hepatic allograft venous congestion.
2. Initial postoperative hypotension may be a result of PHTN, PPHTN, hemorrhagic shock, or cardiomyopathy. Invasive monitors can help discern the etiology.
3. Initiation of immunosuppression beginning with induction therapy will be comprised of steroids, calcineurin inhibitors, and MMF initially.
4. Viral and fungal prophylaxis is necessary and is likely not to be weaned during the first weeks following transplantation.
5. Steroid exposure increases the risk of recurrence of hepatitis C after liver transplantation. MMF exposure can reduce the risk of reinfection with HCV.
6. Many medications will be metabolized more slowly in liver transplant recipients as well as have significant interaction with each other; frequent measurements of drug levels and adjustments should be made.
7. Fever, leukopenia, or mental status changes should illicit a prompt evaluation of opportunistic infections, hepatic artery thrombosis, as well as the potential for rejection.

ANNOTATED REFERENCES

Klouche K, Amigues L, Massanet P, et al. Outcome of renal transplant recipients admitted to an intensive care unit: a 10-year cohort study. *Transplantation* 2009;87:889–895.

This single-center study reports a retrospective analysis of all renal transplant patients admitted to their ICU over the 10-year period 1997 to 2007 to evaluate outcome and determine predictive factors of outcome. Of their patient population, 57 were admitted over this time period, equaling a rate of 17 per 1000 patient-years. Mortality was twice the mortality of an unselected population of ICU patients (40% vs. 20%). Predictors of mortality included need for mechanical ventilation and mean arterial pressure.

Jeloka TK, Ross H, Smith R, et al. Renal transplant outcome in high-cardiovascular risk recipients. *Clin Transplant* 2007;21:609–614.

The authors report their experience with patients undergoing renal transplant who have risk factors for cardiac morbidity. They included 429 patients with roughly 10% suffering posttransplant cardiac events. Patients who were high risk (pretransplant angina, myocardial infarct, or angiogram history) were more likely to die post transplant. Intervention with stenting or bypass grafting did not reduce the risk of postoperative cardiac events.

Thomas MC, Mathew TH, Russ GR, et al. Perioperative blood pressure control, delayed graft function, and acute rejection after renal transplantation. *Transplantation* 2003;75:189–195.

This single-center study evaluated the relationship of perioperative blood pressure control to delayed graft function and acute rejection, and identified a significant relationship between better blood pressure control, reduced rejection, and improved graft function.

Matas AJ, Humar A, Gillingham KJ, et al. Five preventable causes of kidney graft loss in the 1990s: a single-center analysis. *Kidney Int* 2002;62:704–714.

This large, single-center review identified five major causes of renal graft loss over 10 years (1990–1999) in the 1467 primary renal transplants performed at this institution. These causes included thrombosis, acute rejection, chronic rejection, death with function, and non-compliance. Death with function and thrombosis were the most common causes of graft loss in the first year after transplant.

Catena F, Ansaloni L, Gazzotti F, Bertelli R, et al. Gastrointestinal perforations following kidney transplantation. *Transplant Proc* 2008;40:1895–1896.

The authors of this single-center study report their experience with GI complications in 1611 patients following kidney transplantation. Perforations of the colon (n = 21), small bowel (n = 15), duodenum (n = 6), and stomach (n = 4) were noted. GI perforation was associated with a 24% mortality rate, and nearly 50% of the perforations were associated with a period of high-dose immunosuppression.

Evens AM, David KA, Helenowski I, et al. Multicenter analysis of 80 solid organ transplantation recipients with post-transplantation lymphoproliferative disease: outcomes and prognostic factors in the modern era. *J Clin Oncol* 2010;28:1038–1046.

This multicenter analysis included patients from four transplant centers over a decade who developed posttransplant lymphoproliferative disease. In this cohort of patients (n = 80), mean time to development of PTLN was 48 months post transplant. Three-year survival rate was 62%, and survival with rituximab was significantly improved compared to without (73% vs. 33%). Poor prognostic indicators for outcome included CNS involvement, bone marrow involvement, and hypoalbuminemia.

Intestinal and Multivisceral Transplantation: The Ultimate Treatment for Intestinal Failure

Geoffrey J. Bond, Rajesh K. Aneja, Sarangarajan Ranganathan, Kathryn Felmet, Jeffrey A. Rudolph, Jorge Reyes, and George V. Mazariegos

Intestinal and multivisceral transplantation remains a dynamic process, moved forward by advances in the multidisciplinary care of intestinal failure, surgical techniques, innovative immunosuppressive strategies, and an improved understanding of intestinal transplantation immunology. More recently, great strides have been made in the medical and surgical management of patients with intestinal failure so that the number of patients undergoing intestinal transplantation has decreased.¹ However, no matter how good the nontransplant management of intestinal failure becomes, there will inevitably remain a group of patients in whom transplantation is the ultimate and final component of their intestinal care. Recognition of intestinal transplantation as an established modality for select intestinal failure patients combined with improved outcomes since the early 2000s had previously led to an increasing number of candidates referred for intestinal transplantation each year (Fig. 160-1). This coincided with the development of multidisciplinary units, where patients could be managed the most appropriately, with medicine, surgery, or transplantation and often a combination of these. The goal is that patients likely to require transplantation will be listed, followed, and transplanted at the optimum time after weighing the risks and benefits and complications of each of these modalities. In the United States alone, nearly 1000 patients were alive with a functioning intestinal allograft as of December 2013.² Although the time interval between listing and intestinal transplant has decreased over the past decade (Fig. 160-2), wait list mortality remains high, particularly for infants and adults with concomitant liver failure.³ Immunosuppression for intestinal and multivisceral transplantation commonly involves some form of perioperative antibody induction, although many centers now tailor induction and management protocols to individualize strategies based on each patient's situation, often by employing immunologic testing, in particular cross-matching and donor-specific antibody reactions, to help determine optimum strategies. The future of intestinal transplantation depends on the prevention and treatment of chronic rejection in isolated intestinal allografts, which continues to be a fundamental barrier to achieving successful long-term outcomes and is the ongoing subject of rigorous investigation. Long-term data on nutritional outcomes and transplantation morbidity help further determine the optimal timing and role of intestinal and multivisceral transplantation in patients with intestinal failure.

MANAGEMENT OF INTESTINAL FAILURE

Intestinal failure is clinically defined as the loss of nutritional autonomy secondary to bowel dysfunction and the need for parenteral nutrition (PN) for more than 28 days. Patients with intestinal failure are initially managed by administration of PN through central venous access. The duration of intestinal failure is variable and, in certain patients, unpredictable, from short-term to lifelong, and depends largely on the adaptation capacity of the remaining viable intestine, which in itself is dependent on variable factors such as patient age and underlying diagnosis. Improved long-term outcomes in PN-dependent pediatric patients have been reported recently by single centers.^{4,5,6} Nonetheless, there remains a significant subset of patients who develop irreversible

intestinal failure and require indefinite PN therapy with its attendant complications. Intestinal transplantation has proved to be lifesaving in this later group of patients with irreversible intestinal failure who suffer complications from administration of PN.⁷

Optimal management of patients with intestinal failure is achieved after a detailed multidisciplinary evaluation.^{8,9} Obtaining a comprehensive history is critical and must include birth details (such as prematurity) and disease history, complicating comorbid medical history, past surgical procedures, infections, number and location of previous central venous lines, presence of central venous thrombosis, a detailed nutrition history including duration of PN, details of PN prescriptions, and maximal enteral feeding tolerance and its trajectory (still advancing or static) as well as medication history and frequency/volume of stools. A careful history obtained and physical examination performed by the intestine rehabilitation team is critical to the process of achieving a complete pretransplant workup. Further investigations include blood tests, upper gastrointestinal (GI) contrast study with small bowel follow-through, contrast enema if indicated, abdominal sonogram to assess for hepatosplenomegaly, and an ultrasound exam of central venous anatomy. Occasionally, endoscopy with small intestinal aspiration for quantitative microbial culture and mucosal biopsy is recommended. In equivocal cases, liver biopsy is recommended if there is evidence of liver dysfunction or portal hypertension to determine if concomitant liver containing transplantation is required.

Management of patients with intestinal failure focuses on optimization of gut adaptation and recovery of intestinal function to achieve enteral autonomy. With improved management of PN and minimization of complications, longer duration of PN can be achieved to allow for gut adaptation. There has been renewed interest in enterocyte trophic factors, including growth hormone and more recently glucagon-like peptide (GLP2),^{10,11} which has shown some benefit in adults, with a pediatric trial ongoing. Surgical therapies that have a role in adaptation after intestinal failure include autologous reconstructive surgeries (repair enterocutaneous fistulae and disconnected bowel) and bowel lengthening procedures,¹² such as the Bianchi procedure¹³ and serial transverse enteroplasty (STEP).^{14,15} Alternatively, if gut dysfunction is considered irreversible, management of these patients concentrates on maintaining optimal growth in children and nutritional repletion in adults to prepare them for likely intestinal transplantation. Recently, there has been a shift in timing of intestinal transplantation, focused more on the individualized risks and complications of PN versus intestinal transplantation. In other words, if patients, especially children where there still may be hope for further adaptation, are stable on PN, with no significant complications, then continuing on this line and deferring transplant is quite reasonable.

Small bowel bacterial overgrowth (SBBO) is a common clinical problem in patients with intestinal failure and is treated with a variety of antibiotic regimens. To date, no comparative studies are available to enable an evidence-based approach to treat SBBO. The use of metronidazole for anaerobic overgrowth, combined with trimethoprim and sulfamethoxazole or an oral aminoglycoside for gram-negative organisms, is a common theme. Metronidazole monotherapy is used if the

FIGURE 160-2 ■ **Median time to transplant for intestine waiting list registrants, 1999-2008.** (Adapted from Mazariegos GV, Steffick DE, Horslen S, et al. Intestine transplantation in the United States, 1999-2008. *Am J Transplant* 2010;10:1020-1034.)

dominant symptoms suggest predominantly anaerobic overgrowth (such as bloating, increasing diarrhea, and D-lactic acidemia). The extreme sensitivity of anaerobes to oxygen makes the use of small bowel aspirate cultures relatively unreliable as a means of microbial surveillance or indication to treat SBBO. Probiotics such as *Lactobacillus* and *Saccharomyces* have been used in an attempt to limit SBBO. Given the absence of randomized evidence to support the efficacy of probiotics, coupled with reasonable concerns about impurities and possible contamination with other bacteria (e.g., *Leuconostoc*), the use of probiotics is controversial and mostly discouraged in patients with central venous catheter access and intestinal failure and especially after transplantation due to increased immunosuppression.

Parenteral nutrition-associated liver disease (PNALD), also referred to as *intestinal failure-associated liver disease* (IFALD), remains a critical problem in this patient population, affecting infants disproportionately. The 1-year mortality of patients with PNALD exceeds 80% in the absence of PN weaning or transplantation. Although not always feasible, the best strategy to prevent and treat PNALD involves a commitment to the advancement of enteral nutrition. Despite a conscientious approach to PN therapy, many children and adults still develop cholestasis relatively early in their clinical course. Prevention and timely treatment of infection, minimizing SBBO, preventing overfeeding with dextrose, providing adequate amino acids, cycling PN, or providing PN-free days when possible are probably important measures to slow the progression of PNALD.¹⁶ Stasis of bile in the nonstimulated biliary system and gallbladder can lead to sludge buildup and cholelithiasis. In the authors' experience, cholecystectomy may be beneficial to minimize the risks of developing biliary obstructive episodes and pancreatitis and should be considered early in any operative course as part of a combined procedure. If long-term use of PN is to be expected, then cholecystectomy on its own is rarely done as it rarely improves liver function and is not indicated for PNALD alone. Bowel reconnection, even in patients with very short guts, may relieve some of the high pressure in the upper GI tract and issues of reflux cholangitis. This, in association with the cholecystectomy, may allow for long-term improvements in liver function. None of the components of standard PN solutions have been conclusively shown to cause or contribute to PNALD, but excess glucose and improper ratios of glucose to amino acid have been associated with hepatic steatosis. Interest in the manipulation of the lipid component of PN has led to lipid minimization protocols with the reduction of soy-based lipid solutions and even their eventual removal by substituting with Omegaven (a fish oil-based, intravenous [IV] lipid solution rich in omega-3 fatty acids). Omegaven is, as yet, not FDA approved and is currently available as a study drug under an IRB-approved compassionate use protocol. Substantive evidence that these measures retard or reverse the progression of liver disease has not yet been definitively demonstrated, and although bilirubin levels are lowered, it is not known if improvement in hepatic fibrosis occurs at the molecular level.^{17,18,19} Other options, such as SMOF (soybean oil, medium-chain triglycerides, olive oil, fish oil), which has been utilized for many years in Europe, is currently in trial in the United States and may offer another improved alternative in patients with PN dependence. In some circumstances, either due to poor weight gain and need for increased calories or concerns for essential fatty acid deficiencies, it may be necessary to add, but not entirely substitute, fish oil-based lipids for soy-based solutions. However, this is administered to patients in whom liver function tests demonstrate abnormalities.

In addition to PNALD, patients on long-term PN are at risk of developing metabolic bone disease (MBD). Associated with an insidious onset of bone pain that can become quite severe, patients with MBD will present with normal serum calcium, phosphorus, vitamin D, and parathyroid hormone, but with hypercalciuria. Nontraumatic spinal and rib fractures have been reported in these patients. To optimize bone maintenance in patients on PN, it is important to include calcium in parenteral formulations, prevent metabolic acidosis, and minimize aluminum contamination. Symptoms of MBD tend to resolve only after stopping PN.

Many intestinal transplant recipients will require intensive care unit (ICU) management during the pretransplant period, although the number of patients being transplanted from home (outside of a hospital setting) has increased with improved medical management and resulted in improved outcomes in this subset of patients.¹ Sepsis and GI hemorrhage are common reasons for ICU admission in patients with intestinal failure. Blood products, though necessary in the resuscitation of GI hemorrhage, should be used judiciously in the absence of acute bleeding. Pretransplant exposure to blood products, particularly platelets, can predispose intestinal transplant recipients to developing antibodies and can place them at a higher risk of developing antibody-mediated rejection after transplantation. Leukoreduced blood products may be preferable in patients awaiting transplant.

Central line–associated bloodstream infections (CLABSI) unfortunately are common in PN-dependent patients. All attempts should be made to avoid this event, with fastidious central line care at the core of the matter, with strategies like antibiotic and ethanol locks²⁰ playing an important role. As the incidence and degree of liver dysfunction lessens with improved PN management, long-term therapy is still required. One of the determining factors to move forward with transplantation is loss of venous access. Hence, although infection (especially fungal and life-threatening gram-negative infections) may necessitate removal of a tunneled central venous catheter, all attempts at salvaging the line, or at least the venous site, should be considered. In particular, smaller pediatric patients and patients with a history of thrombosis may have limited venous access, necessitating preservation and treatment through an infected line. Percutaneous lines should be placed with caution in these patients as great vessels may no longer be patent, and the trauma to the remaining vessels may have serious consequences. Many surgeons, anesthesiologists and intensivists now place central lines under ultrasound guidance, although the more difficult and chronic issue lines are best served in interventional radiology with their vast cadre of specialized techniques. Ultrasound evaluation of deep veins to assess for patency is notoriously variable and often unreliable, and in difficult or concerning cases venography remains the gold standard. Mapping should be considered before excessive loss of venous access occurs.

Nutritionally deplete patients are relatively immune suppressed and prone to severe community-acquired infections. Pediatric patients with intestinal failure and IFALD are at increased risk of respiratory failure even with common viral infections. Since children have a compliant chest wall, increased abdominal girth creates a mechanical disadvantage even during normal tidal volume breathing. In the setting of pulmonary infection, volume overload, or decreased cardiac output, the work of breathing can lead to fatigue.

■ INDICATIONS FOR TRANSPLANT

The goals of the transplant team are to determine whether the patient may benefit from transplantation, assess alternatives to transplant, evaluate any contraindications to transplantation, and provide education to the patient about the complex process of undergoing transplantation. After evaluation by the multidisciplinary team and open and frank discussion among all the team members, the usual result is one of three choices: (1) patient may be followed closely as an intestinal care patient and listing status deferred depending on progress, (2) listed as a status 2 recipient to accrue time on the list while awaiting possible medical improvement or bowel adaptation but realizing that transplantation is still quite likely, or (3) as a status 1 intestinal recipient if the patient has met criteria for complications of irreversible intestinal failure or as a liver intestine recipient if the patient is deemed to have irreversible intestinal failure and associated irreversible significant liver dysfunction for immediate consideration where criteria make transplantation inevitable.

In October 2000, the Center for Medicare and Medicaid Services approved intestinal, combined liver-intestine, and multivisceral transplantation as a standard of care for patients with irreversible intestinal failure who could no longer be maintained with PN. Intestinal and

TABLE 160-1

Indications for Intestinal and Multivisceral Transplantation

| PEDIATRIC PATIENTS | ADULT PATIENTS |
|--------------------------------|---|
| Volvulus | Superior mesenteric artery thrombosis |
| Gastroschisis | Crohn's disease/irritable bowel disease (IBD) |
| Necrotizing enterocolitis | Desmoid tumor |
| Pseudo-obstruction | Volvulus |
| Intestinal atresia | Trauma |
| Microvillous inclusion disease | Familial polyposis |
| Hirschsprung's disease | Budd-Chiari disease |
| Trauma | Intestinal adhesions |
| | Pseudo-obstruction |
| | Radiation enteritis |

multivisceral transplantation are considered for patients with irreversible intestinal failure who fail PN therapy due to complications, such as recurrent life-threatening catheter infections, multiple venous thrombosis limiting line access, and impending liver failure. Other criteria include those who cannot tolerate quality-of-life limitations associated with PN therapy or who have no chance of intestinal rehabilitation either due to extreme gut loss or no hope of restoration of function of the gut that exists. Subsequently, there has been discussion within the intestinal transplant community as to whether the above criteria and timing of these events need to be reconsidered or modified. The myriad causes of bowel dysfunction can be subcategorized into acute and chronic pathophysiologies. Common causes of acute dysfunction include necrotizing enterocolitis, volvulus, and mesenteric thrombosis. Common causes of chronic dysfunction include Crohn's disease and radiation enteritis. These disease processes can alternatively be classified as either surgical due to resection leading to short bowel syndrome (SBS) or nonsurgical due to congenital enterocyte disorders leading to dysmotility or malabsorption. Unlike patients with SBS, patients with nonsurgical causes of intestinal failure may have native intestines with normal gross morphology and anatomic length. [Table 160-1](#) lists the already well-described clinical indications for intestinal and multivisceral transplantation.

Owing to the particularly high morbidity and mortality of children with IFALD, increasing efforts have been made by the pediatric medical community to optimize timing of referral of these patients to specialized intestine failure rehabilitation centers and transplant centers to improve overall outcomes. A recent expert consensus panel²¹ recommended the following pediatric criteria for consultation or referral for small bowel transplant assessment: (1) children with massive small bowel resection, (2) children with severely diseased bowel and unacceptable morbidity, (3) continuing prognostic or diagnostic uncertainty, (4) microvillous inclusion disease or intestinal epithelial dysplasia, (5) persistent hyperbilirubinemia (>6 g/dL), (6) thrombosis of two of four upper body central veins, and (7) the request of the patient or family. This initiative, to a large extent, has been relatively successful in breaking down previously held prejudices and allowed for prompt and, at times, very early evaluation. This in turn has allowed for more coordinated expert multidisciplinary management of these patients, and with fewer patients now heading into liver failure with improved preservation of the liver, it gives the medical and surgical teams more time to let the native bowel grow, so that more patients, even after 5 or more years of PN therapy with ultrashort guts are eventually able to wean off of PN that previously would never have been given this chance.

Transplantation is unlike any other surgical procedure in that it is rarely an isolated event, unlike general surgical procedures, and has significant short- and long-term medical and surgical issues that need to be considered. Nowadays, as the overall management of PN improves, the indication and timing of transplantation become a

balancing act, trying to weigh the risks and complications of PN versus the potential short- and long-term risks of intestinal transplant.

EVALUATION FOR TRANSPLANT

For both children and adults, the evaluation of intestinal and multivisceral candidates usually begins as an inpatient process due to the complexity of the case and the need for many different services to see the patients and investigations that may be required. Most intestinal failure units utilize multidisciplinary teams that assess patients during evaluations. This comprises the GI team, other medical teams as indicated (cardiac, renal, genetic, immunology, pulmonology, etc.) general surgery (especially pediatric surgery), transplantation, and many allied services including psychology, social work, pharmacy, and others as indicated in each case. Transplant teaching is a vital component, as is determining fiscal ability and supportive structures for potential recipients. Each team provides recommendations, and in particular the GI team may make recommendations with the PN and IV medications that may be quite beneficial to the patient and the referring team. At times, especially in a multidisciplinary center with both good pediatric surgical and transplant skills, these patients may undergo surgical exploration and attempts at reconstruction and/or bowel lengthening procedures prior to transplantation. These are done with an attempt to either avoid transplantation, or at least minimize the need for PN and delay the need for transplantation, or to make the conditions at transplant better (i.e., obtain colonic growth and health in previously disconnected patients or resecting enteric fistulae/intraabdominal abscesses that may be contributing to sepsis).

Having a surgeon well versed in medical management strategies, able to operate as a general surgeon to try to help restore enteral autonomy by surgical means, and be able to put the patient up for transplant is advantageous for both the patient and intestinal failure unit, allowing for more aggressive surgical interventions to try to avoid or delay transplantation.

Determining which type of allograft to use in patients with intestinal failure involves a comprehensive evaluation of the function and anatomy of the remaining bowel along with other abdominal organs. Intestinal failure patients are considered candidates for isolated intestinal transplant (with or without colon), combined liver and intestine transplant, multivisceral transplant (including liver, stomach, duodenum, pancreas, and small bowel with or without colon), or modified multivisceral transplant that excludes the liver. There has been ongoing debate in the transplant community regarding the above nomenclature; however, from a practical and immunologic point of view the major differentiation is the inclusion of the allograft liver as part of the transplant bloc. Whether to perform simultaneous hepatic replacement remains a challenging decision even to experienced transplant surgeons, particularly for patients with borderline liver dysfunction and a biopsy that shows fibrosis (Ishak level 3-4 and above) and some degree of synthetic dysfunction suggestive of portal hypertension. Nevertheless, it must be realized that the classic symptoms and signs of impending liver failure may not be the same in patients with no intestine, and the use of Omegaven may make the bilirubin at least look relatively normal. This also impacts the MELD and PELD score in these potential recipients, hence the “supplemental” points added to their total when the intestine is added to the liver transplant listing. This has been allowed in the pediatric population for some time now but remains a vexed issue in the adult population. The key factors in determining whether to perform liver transplant in patients with intestinal failure are the extent of portal hypertension and the severity of parenchymal liver disease. In general, patients with mild portal hypertension should be cautiously considered for isolated intestinal transplant. Under these circumstances, it is mostly recommended that venous outflow from the intestinal allograft bypass the portal circulation and be drained to the recipient systemic circulation through the inferior vena cava. This is especially relevant as there has been no documented proof that portal drainage is more beneficial or that relative portal and mesenteric hypertension may have deleterious effects

on intestinal allograft function. The other predicament is the patient with marginal intestinal length who may, under ideal circumstances and more time, be able to adapt and come off of PN but the liver has undergone such considerable damage that it needs to be replaced. In this circumstance, liver transplantation in the face of short gut syndrome can and has been done but is fraught with potential dramatic consequences and the potential need for liver and intestine retransplantation if it is not successful.

TRANSPLANTATION PROCEDURES

Brief descriptions of recipient operations are provided below. The multivisceral donor procurement operation has previously been well described.²² It is important to note that to a large extent, the future course post transplant is significantly determined by the quality of the donor and success of the donor recovery and back table preparation. The intestine is perhaps the most sensitive donor organ and prone to ischemic events either by nature of the cause of death or due to pharmacologic agents (pressors) that are used to support the donor leading up to and after brain death. It is thought that damage to the bowel sets up an inflammatory cascade that in turn makes the organ more immunogenic, or at least more susceptible to a rejection episode once it is reperfused in the recipient. Hence, the recipient surgeon is extremely judicious in the selection of a suitable donor and the number of acceptable donors is restricted. Other factors that play into this decision include blood group (generally identical), size-matching issues due to restricted abdominal domain (reduced grafts have been shown to have short- and long-term issues) and, some potential crossmatch issues (especially in retransplant patients). Thus, it is clear why the intestinal allograft is one of the more infrequently recovered allografts.

Isolated Intestinal Transplant

For isolated intestinal transplants (Fig. 160-3), the donor intestinal graft (jejunum and ileum) is procured along with donor vascular conduits, including an artery (iliac and/or carotid) and a vein (iliac, occasionally jugular). The donor superior mesenteric vessels are occasionally anastomosed directly to the recipient superior mesenteric artery and vein if adequate length is achieved. More commonly,

FIGURE 160-3 ■ Isolated intestinal transplant.

interposition vascular conduits are anastomosed to the recipient infrarenal aorta and recipient superior mesenteric vein (portal drainage) or inferior vena cava (systemic drainage) to provide sufficient length and proper orientation for the allograft.

The intestinal reconstruction involves a proximal duodeno- or jejunojunction, depending on individual recipient considerations of remnant bowel viability and anatomy. The distal end of the intestinal allograft may be used as a permanent end ileostomy if the recipient has no remaining viable colon or may be anastomosed to the remnant colon, leaving a short portion of allograft distal to the enterocolic anastomosis to bring out as a temporary end ileostomy (Brooks-type ileostomy) that allows access to the bowel for endoscopic surveillance and mucosal biopsies. Colonic transplantation with the small bowel has been utilized in some centers with good results, especially in situations where the native colon is very short or nonfunctional (such as Hirschsprung's disease or pseudo-obstruction). In this case, a loop ileostomy is formed so that the small bowel can be biopsied and the colon normally brought out as an end colostomy, or if anastomosed to the remaining colon, a loop colostomy may be formed as well. In patients with gastric dysmotility, although a stomach inclusive allograft may be ideal, due to donor availability (size and/or anatomic vascular aberrations) it may not be recoverable; hence a gastrojejunostomy may also need to be performed as an alternative to drain the stomach. Single or multiple feeding tubes (gastrostomy tube, jejunostomy tube, and combined gastrojejunostomy tube) may be placed based on multiple considerations including recipient pretransplant oral intake capacity and dysmotility issues.

Combined Small Bowel and Liver Transplant

For combined small bowel and liver transplants (Fig. 160-4), the recipient hepatectomy is routinely performed with preservation of the native retrohepatic inferior vena cava. The recipient foregut including stomach, native pancreas, and proximal duodenum is also preserved and its outflow maintained with a permanent end-to-side portocaval shunt. The composite donor allograft includes the primary organs (liver and small bowel) as well as the donor duodenum and pancreas, allowing for maintenance of donor hepatobiliary continuity. Arterial inflow to the composite donor allograft is achieved using an arterial interposition conduit from the recipient infrarenal aorta to the reconstructed donor aorta placed onto the Carrel patch of donor celiac artery and superior mesenteric artery. Allograft venous outflow via the suprahepatic inferior vena cava commonly involves the well-described "piggyback" technique, anastomosing donor suprahepatic inferior vena cava to the confluence of the recipient hepatic veins and cava. Occasionally, a "standard" bicaval anastomosis is performed. Intestinal reconstruction is performed in a similar fashion to an isolated intestinal transplant, mostly with the upper anastomosis being a jejunojunction. Feeding tubes are placed as indicated.

Full Multivisceral Transplant

In the majority of cases of full multivisceral transplant procedures (Fig. 160-5), prior to implantation the recipient distal stomach, duodenum, pancreas, liver, and remaining small bowel are resected. The recipient inferior vena is routinely meticulously preserved. The absence of remaining foregut or midgut precludes the need for portocaval shunt. Vascular inflow is similar to composite liver-bowel transplant but now includes celiac inflow to the stomach as well. Vascular outflow is identical to composite liver-bowel transplant. The donor spleen is removed from the composite allograft on the back table prior to reperfusion.

Intestinal reconstruction is performed proximally with a gastrogastrostomy anastomosis, and the distal anastomosis is similar to previously described intestinal transplants. To avoid gastric outlet obstruction due to vagal denervation, a Heineke-Mikulicz pyloroplasty is routinely performed after reperfusion. Feeding tubes are placed as indicated.

A Native portocaval shunt draining native foregut into recipient vena cava

B

FIGURE 160-4 ■ Combined liver and intestinal transplant. A, Portocaval shunt draining native foregut. **B,** Combined liver and intestinal transplant with feeding jejunostomy.

Modified Multivisceral Transplant

A "modified" multivisceral transplant (Fig. 160-6) involves transplantation of a full composite allograft without a liver. The recipient liver is preserved along with its vasculature and the extrahepatic biliary system with duodenum, pancreas, and spleen. Vascular conduits are used routinely (Fig. 160-7). If the native enterohepatic biliary system is intact, the native duodenum or jejunum is drained into the allograft duodenum or jejunum. If, however, the procedure involves disruption of hepatobiliary continuity, the native bile duct can be drained via Roux-en-Y hepaticojejunostomy constructed from donor intestinal allograft (often the case in children where the donor bile duct is very small), or in adults and older children via a choledochoduodenostomy (duct-to-duct) anastomosis.

POSTOPERATIVE MANAGEMENT

Advances in the technical aspects of intestinal and multivisceral transplantation have occurred in parallel with improvements in intraoperative monitoring and postoperative critical care management of these challenging patients.

FIGURE 160-5 ■ Full multivisceral transplant.

FIGURE 160-6 ■ Modified multivisceral transplant.

FIGURE 160-7 ■ Vascular conduit extensions for modified multivisceral transplant.

Ventilatory Management

Extubation is commonly achieved within 48 hours of the transplant operation in adult patients. Mitigating factors that might delay extubation include graft malfunction, delayed abdominal wall closure, volume overload, sepsis, organ failure, and surgical complications such as bleeding. In children, delayed abdominal wall closure is commonly necessary due to allograft size constraints and swelling post reperfusion and requires continued neuromuscular blockade and mechanical ventilation while diuresis is performed. Given that recipients tend to be nutritionally compromised preoperatively and that intestinal and multivisceral transplant operations are relatively long in duration (8 to 18 hours), a careful assessment of weaning parameters prior to extubation is essential. Changes in intraabdominal pressure and abdominal girth may adversely affect respiratory mechanics, leading to rapid, shallow breathing. These problems are most common in children, in small adults who receive large allografts, and in patients whose course is complicated by large-volume ascites. Pleural effusions are common due to nutritional depletion with hypoalbuminemia and intraoperative manipulation of the diaphragm. Although attempts to overcome them by diuretics may be attempted, thoracentesis and placement of pleural tubes often are necessary.

Renal Function

It is common for intestinal transplant recipients to demonstrate some degree of renal dysfunction pretransplant, owing to multiple episodes of sepsis with hypotension, the side effects of antibiotics, chronic dehydration, and hepatic dysfunction. Although patients receive significant volumes of fluid during the long course of the transplant operation, intravascular volume depletion can be a problem in the immediate posttransplant period. Significant fluid volume may accumulate in the intestinal allograft secondary to preservation injury (peaking at 48 to 72 hours), and large-volume ascites production due to mesenteric lymphatic leakage may occur. Either of these processes can lead to profound and sometimes underappreciated intravascular volume depletion and can worsen the nephrotoxicity of immunosuppressive agents and antibiotics.

Maintenance of ideal volume status is challenging in these patients, and interventions should be directed at optimizing cardiac output and organ perfusion. Extravascular volume overload is common and should be interpreted with caution, particularly in the immediate posttransplant period. In patients with impaired renal function or high tacrolimus drug levels, urine output may not be an accurate indicator of perfusion. Skin perfusion, mixed venous oxygen concentration, and serum lactate are useful surrogates. Since intestinal transplant recipients are commonly nutritionally deplete, use of 5% albumin as a volume expander may be preferable to larger volumes of crystalloid solution. In patients with large-volume stoma output or ascites drainage, standing orders for fluid replacement may be necessary. Balancing adequate volume resuscitation with the avoidance of volume overload in the setting of baseline renal dysfunction can be a significant challenge that requires considerable clinical experience and meticulous attention to detail.

Infection Control

Recipients of intestinal or multivisceral transplants will routinely receive prophylactic broad-spectrum antibiotics intra- and post transplant. Any history of nosocomial infections before transplant should be addressed with administration of the appropriate specific antibiotics. Colonizing organisms growing from enterocutaneous fistula tracts should also be covered appropriately. Selective bowel decontamination with nonabsorbable oral antibiotics is performed routinely in the donor and in some intestinal transplant recipients. Some centers also perform surveillance stool cultures on a regular basis post transplant.

Translocation of bacteria or bacterial toxins from the intestine into the bloodstream can cause sepsis or systemic inflammatory response syndrome (SIRS). A history of repeated exposure to broad-spectrum antibiotics leads to colonization with multiple resistant organisms in many intestinal transplant recipients. Empiric antibiotic therapy for sepsis should include coverage for common enteric organisms and should take into account a history of antimicrobial resistance. Episodes of translocation occur most commonly during acute rejection, when the mucosal barrier of the allograft has been compromised but can also be demonstrated with enteritis associated with Epstein-Barr virus (EBV) and cytomegalovirus (CMV) infection. In the absence of positive blood cultures to direct antibiotic therapy, organisms growing from quantitative stool cultures in significant numbers ($>10^8$ colony-forming units [CFU]/mL) in patients with sepsis or acute cellular rejection may be considered potential causes of bacteremia and may be treated with IV antibiotics. The high incidence of renal dysfunction in intestinal transplant recipients should prompt use of nonnephrotoxic antibiotics when possible and careful monitoring of antibiotic levels when necessary.

One of the major complications post transplantation is opportunistic infections, be they viral or fungal. Fungal infections must always be considered in recipients with fevers and negative cultures, and often appropriate antifungal treatment is commenced empirically pending extended culture results and imaging studies.

Antiviral Prophylaxis

Opportunistic viral infections play a significant factor in postoperative complications. Antiviral prophylactic strategies have evolved with intestinal transplantation. Viral infections can cause significant morbidity, especially in pediatric recipients in the early postoperative period. Common pathogens include CMV, EBV, herpes simplex virus (HSV), adenovirus, and influenza viruses. Many pediatric recipients have no prior protective exposure to these viruses, so primary infection occurs in these patients while they are highly immunosuppressed. Recent advances in prophylaxis and preemptive therapy have significantly decreased early morbidity associated with EBV, CMV, and HSV, lowering the incidence of clinically significant infections to less than 5%. Lack of definitive treatment for infections with respiratory viruses such as influenza and adenovirus in the early postoperative period

can be catastrophic because of clinical sequelae including disseminated viremia, necrotizing pneumonitis, and bacterial superinfection. The currently recommended anti-CMV prophylaxis includes a 2-week course of IV ganciclovir with concomitant administration of cytomegalovirus-specific hyperimmune globulin (Cytogam). The IV dose for ganciclovir is 5 mg/kg twice daily. The dose for Cytogam is 150 mg/kg, administered 2, 4, 6, and 8 weeks after transplant, and 100 mg/kg/d at 12 and 16 weeks after transplant, except in the case of donor CMV negative to recipient CMV donor negative. Close monitoring of CMV and EBV polymerase chain reaction (PCR) is performed frequently post transplant and spaced out moving away from the time of transplant and as indicated.

Nutritional Support

Immediate posttransplant nutritional support is administered using standard PN, which is tapered gradually as enteral feeding is advanced. Tube feedings with isotonic formula are started based on clinical determination of intestinal allograft function. In the authors' experience, most intestinal transplant patients especially children, do not voluntarily ingest adequate amounts of nutrition in the early postoperative period. To achieve maximal nutritional repletion, tube feeding is usually required once the intestinal tract becomes functional. Resistance to oral feedings is a particular clinical challenge in younger pediatric recipients, many of whom demonstrate oral aversion. This should be assessed and attempts should be made pretransplant to avoid or overcome this issue.

Immunosuppression

Although a variety of combinations of immunosuppressive drugs have been used in intestinal transplant recipients, most patients are maintained on tacrolimus (Prograf [Astellas, Tokyo, Japan]) therapy along with other adjunctive medications. Organ Procurement and Transplantation Network (OPTN) data show that 99% of intestinal transplant recipients receive tacrolimus as part of their maintenance immunosuppression at the time of posttransplant discharge. Moreover, during the first posttransplant year, only a select number of patients are taken off of tacrolimus (mostly for complications perceived to be related to tacrolimus), with nearly 97% remaining on tacrolimus-based therapy. Recent International Intestinal Transplant Registry data suggest that rapamycin may have some improved outcomes and could be used as an alternative or in combination with tacrolimus. However, further research is needed to validate these data. Currently, the most common regimen at 1 year post transplant is tacrolimus in combination with steroids, with tacrolimus monotherapy being the second most common. In some patients who have had significant rejection, a third agent may be employed, in addition to tacrolimus and steroids, like mycophenolate mofetil (MMF) or Imuran.

Two classes of immunomodulatory drugs have been introduced for intestinal transplantation and have been associated with improvements in 1-year patient and graft survival. Depleting antilymphocyte antibody therapies include rabbit antithymocyte globulin (rATG, Thymoglobulin [Genzyme Corp., Cambridge, Massachusetts]) and rarely now alemtuzumab (Campath-1H [Genzyme Corp.]). The individual use of these agents by high-volume single centers has demonstrated improved short-term survival and decreased rejection rates as well as severity.^{23,24,25} Associated with similar improvements in survival and decreased incidence of acute rejection and severity, induction with the nondepleting interleukin (IL)-2 receptor antagonists, daclizumab (Zenapax) and basiliximab (Simulect), has also gained increasing acceptance by many intestinal transplant programs. In select cases of suspected antibody-mediated rejection (class II DSA and evidence of histologic injury), other agents such as rituximab or bortezomib may also be utilized (often in addition to pheresis and intravenous immunoglobulin [IVIG]). Immunosuppression for intestinal and multivisceral transplantation now involves perioperative antibody induction in over 60% of cases.

FIGURE 160-8 ■ Enteroscopic findings consistent with acute cellular rejection of intestinal allograft. (Courtesy Kareem Abu-Elmagd, MD.)

Immunologic Monitoring

The gold standard for monitoring and diagnosing rejection in intestinal and multivisceral transplant recipients to date remains routine ileoscopy and proximal enteroscopy with histopathologic examination of multiple random mucosal biopsies. Significant investigation is under way into the development of tools to guide and monitor the immunologic state of intestinal transplant recipients. Ideally, noninvasive markers such as serologic, proteomic, or genomic markers may identify those patients who are at increased risk of rejection and, conversely, those who might benefit from decreased levels of immunosuppression.^{26,27} A recently developed Pleximmune test²⁸ may be helpful, in conjunction with other studies, to determine both those who seem to be at risk for or are currently undergoing rejection, and warrant augmented levels of immunosuppression, or conversely maintain or lower immunosuppression in those who appear to be at lower risk of rejection. Further validation in a larger cohort of patients is needed. Preformed antibody and de novo antidonor-specific antibody measurements may be of assistance in determining the risk of rejection.^{29,30} When technically feasible, the presence of circulating donor cells in the recipient peripheral blood should be serially evaluated after transplantation by either flow cytometry or PCR. Monoclonal antibodies specific for donor HLA class I and II molecules are used for single-color immunofluorescence analysis. The presence of donor-specific antibodies, especially class II, in intestinal transplant recipients may prompt aggressive therapy with augmentation of immunosuppression and addition of other agents and in some circumstances serial plasmapheresis and IVIG until clearance of antibodies has been confirmed. The use of fecal calprotectin or serum citrulline as noninvasive biochemical markers of allograft rejection has certain restrictions in timing of the test and sensitivity issues especially in the initial post-transplant phase and does not appear to be warranted based upon currently available data.^{31,32}

As mentioned, to date the gold standard for detection of rejection is histologic evaluation. Hence, in recipients of intestinal or multivisceral transplants, surveillance endoscopy and biopsy (esophagogastroduodenoscopy [EGD], ileoscopy, colonoscopy) are performed biweekly for the first 4 to 6 weeks post transplant and then weekly for an additional 4 to 6 weeks to monitor for rejection. After the first 3 months post transplant, the frequency of surveillance endoscopies performed in recipients is based upon individual clinical assessments. More frequent scopes and biopsies are performed where clinically or histologically indicated.

ASSESSMENT OF INTESTINAL ALLOGRAFT

The process of examining the anatomic and functional integrity of the intestinal allograft begins in the operating room. The normal intestinal allograft after reperfusion appears pink and nonedematous, with occasional contractions. Altered appearance can be observed in the operating room, especially in the mucosa when the bowel is opened for the anastomosis, and in the proximal jejunal and distal ileal segments using endoscopy postoperatively.

FIGURE 160-9 ■ Ischemia-reperfusion injury. Reperfusion injury is characterized by extensive loss of villi, followed by pronounced regenerative changes of crypt epithelium with conspicuous mitosis, capillary congestion, shortening of villi, and variable degrees of neutrophil-rich inflammatory infiltration.

Surveillance for intestinal allograft rejection in the early postoperative period focuses on clinical evaluation and gross morphologic examination of the stoma and distal ileum. Frequent routine endoscopic surveillance is the most reliable method for achieving an early diagnosis of intestinal rejection (Fig. 160-8). Endoscopic evaluations are performed initially twice a week through the allograft ileostomy. Upper endoscopy is reserved for occasions where clinical changes are not well explained by distal allograft evaluation and biopsy. Common physical changes to the normal appearance of an intestinal allograft include edema, cyanosis, congestion, and increased stomal output. These changes should prompt an immediate workup, with a differential diagnosis that includes preservation injury (Fig. 160-9), sepsis, rejection, enteritis, and vascular compromise (such as thrombosis).

The allograft stomal output is assessed for volume and consistency. Normal stomal output during the early postoperative period is characteristically clear and thin. During the first week post transplant, normal stomal output is 1 to 2 L/d and 40 to 60 mL/kg/d for adult and pediatric recipients, respectively. If these stomal volumes are exceeded in the absence of significant pathology, agents to control volume of output can be started, including loperamide, lomotil, paregoric (tincture of opium), pectin, rarely somatostatin, or oral antibiotics. The presence of blood in the stomal output is an ominous sign and a concern for acute rejection, until proven otherwise. Other causes, however, include anastomotic bleeds in the early posttransplant period, perianastomotic ulcers in the later period, or post biopsy bleeding, which is often seen initially or 5 to 7 days after the biopsy.

Intestinal allograft absorption of nutrients and medications develops gradually and commonly requires several weeks post transplant to improve. Abnormal absorption after approximately 1 month should

prompt an aggressive search for underlying pathology, especially rejection. The ability to maintain whole blood tacrolimus trough levels above 15 ng/mL on oral therapy alone is a good indicator of adequate absorption. In the authors' experience, intestinal transplant recipients demonstrate evidence of sufficient absorptive function at a mean of 28 days after transplantation. Recipients of multivisceral transplants can demonstrate even longer delays until intestinal allograft absorption is well established.

MANAGEMENT OF ALLOGRAFT REJECTION

Allograft rejection (Fig. 160-10) is strongly associated with graft loss and mortality and remains a significant obstacle to achieving successful long-term outcomes for intestinal and multivisceral transplant recipients. Historically, acute cellular rejection was reported in 70% to 90% of intestinal allografts, within 90 days post transplant. In contrast, rejection rates of 30% to 40% are currently reported by large centers due to advances in allograft histopathologic surveillance, immunosuppression, and immunologic monitoring. There does appear to be disparity between some centers where reported rejection rates may be very low (less than 10%) while others still have higher rates (greater than 50%), depending on induction therapies. Unlike liver allograft rejections, the natural history of rejection of intestinal allografts is unforgiving, making early diagnosis and treatment critical for successful reversal of the rejection process.

Until proven otherwise by culture and allograft biopsy, each episode of allograft dysfunction should prompt an expeditious evaluation for acute rejection. No laboratory tests are currently available to warn of allograft dysfunction or rejection for intestinal transplantation although the Pleximmune assay is showing good sensitivity and specificity when utilized in certain criteria, but more assessment is required. Clinical

features of intestinal allograft rejection include nonspecific signs and symptoms such as diarrhea (increased stomal output), nausea/vomiting, fever and abdominal pain. Infectious enteritis and medication-related loose bowel movements are common etiologies of allograft dysfunction that present with a clinical picture similar to allograft rejection. The stoma may become edematous, erythematous, and friable. Endoscopy may demonstrate normal mucosa despite mild to moderate grades of ongoing acute cellular rejection. Moderate to severe rejection of the intestinal allograft usually leads to mucosal inflammation beginning with erythema and friability, progressing to mucosal slough and exudates overlying ulcers, with eventual loss of the mucosal layer. Histologically, there is variable presence of edema in the lamina propria and villous blunting. However, mononuclear cell infiltrates and intestinal crypt apoptosis with regeneration and eventual crypt loss are the hallmark signs of intestinal allograft rejection that establish the diagnosis.

Treatment of intestinal acute cellular rejection initially involves steroids. At the Children's Hospital of Pittsburgh of UPMC, a total dose of approximately 30 mg/kg of methylprednisolone is usually given, either by three boluses of 10 mg/kg/d over 3 days or more routinely by a single bolus and subsequent cycle of tapering doses over a more extended duration. Antilymphocyte antibodies for steroid-resistant rejection include antithymocyte globulin (rATG [rabbit-derived], Thymoglobulin) and rarely nowadays alemtuzumab (Campath-1H [Genzyme Corp.]). Unfortunately, the discontinuation of muromonab CD3 (OKT3, a murine monoclonal anti-CD3 antibody) has been detrimental to the field. Adverse immune-mediated drug reactions to immunomodulatory antibodies can be life threatening. These agents are usually administered to patients with cardiopulmonary monitoring following premedication with steroids, antipyretics, and histamine blockers. In many cases, it is appropriate to initiate therapy in an ICU setting. During and after the treatment of acute rejection, tacrolimus

FIGURE 160-10 ■ Acute cellular rejection of intestinal allograft: mild (A), moderate (B), and severe (C). **A,** Mild acute rejection is characterized by a generally mild and localized inflammatory infiltrate, which tends to be concentrated around small venules in the lamina propria. Mucosa is intact, but crypt epithelium displays evidence of injury: mucin depletion, cytoplasmic basophilia, decreased cell height, nuclear enlargement with hyperchromasia, and inflammatory infiltration. Crypt epithelial apoptosis is increased, usually with more than six apoptotic bodies/10 crypts. If sampled by biopsy specimen, preexisting lymphoid aggregates (Peyer's patches) demonstrate an intense accumulation of activated lymphocytes. Villi are variably shortened, and architecture may be slightly distorted owing to expansion of lamina propria by inflammatory infiltration. **B,** In moderate acute rejection, inflammatory infiltrate is widely dispersed within the lamina propria. Crypt injury and cryptitis are distributed more diffusely than in mild acute rejection, and villi tend to have a greater degree of flattening. Number of apoptotic bodies is greater than in mild acute rejection, usually with focal "confluent apoptosis." Mild to moderate intimal arteritis may be seen. Mucosa remains intact without ulceration, although focal superficial erosions can be present. **C,** Severe acute rejection is distinguished by a marked degree of crypt damage and mucosal ulceration, with lymphocytic infiltration extending deep into allograft wall and involving nerves and ganglia. As a consequence of mucosal destruction, luminal contents gain access to submucosa, prompting a neutrophil-rich infiltrate and an overlying fibropurulent (pseudomembranous) exudate with widespread mucosal sloughing as the final result. Adjacent viable epithelium usually shows rejection-associated changes such as crypt epithelial damage and abundant apoptosis. Severe intimal arteritis or transmural arteritis may be seen.

whole blood levels are maintained around 15 to 20 ng/mL in intestinal and multivisceral allograft recipients. Maintenance steroid therapy usually consists of 1 to 2 mg/kg/d of intravenous methyl prednisolone prednisone converted to oral prednisone, tapered over several weeks to months based on individual clinical assessments. Addition of a third agent such as mycophenolate mofetil (MMF; CellCept [Roche]) or sirolimus (Rapamune) or azathioprine (Imuran) may be indicated if rejection is refractory or recurrent.

A fundamental principle that guides treatment of allograft rejection is the preservation of as much intestinal function as possible. Each episode of rejection likely shortens the longevity of intestinal graft function, so the diagnosis of steroid-resistant rejection in intestinal allografts must be made in a more timely fashion than in a regenerating organ such as the liver. Antilymphocyte therapy in response to a diagnosis of steroid resistance will rapidly reduce the overall number of immunocompetent cells and is usually a highly effective treatment for steroid-resistant rejection. Antilymphocyte therapy must be used cautiously in refractory rejection, since sequential biopsies separated by reasonable time intervals allow for objective confirmation of steroid treatment failure. In isolated cases of intestine recipients with preexisting immune debilitation or a predisposition to a life-threatening illness such as posttransplant lymphoproliferative disorder (PTLD), allograft enterectomy may be safer than escalation of immune suppression and this can potentially be lifesaving.

Antibody-mediated rejection (AMR) of the intestinal allograft (Fig. 160-11) is characterized by intestinal dysfunction, diffuse C4d staining on allograft biopsy, and usually identification of donor-specific antibodies. Treatment of AMR, in addition to thymoglobulin and campath, may consist of plasmapheresis in combination with IVIG and steroids. Rituximab or bortezomib can be used in select recipients.

Chronic rejection remains the most significant complication affecting long-term graft survival. Chronic rejection (Fig. 160-12) is observed in 10% to 15% of pediatric and adult intestinal allografts but occurs more commonly in isolated intestinal allografts. In adult recipients at the University of Pittsburgh, multivisceral transplants including a liver allograft demonstrated a significantly better chronic rejection-free survival compared to the liver-free intestinal and other multivisceral transplant recipients.³³ Risk factors for chronic rejection include type

FIGURE 160-11 ■ Antibody-mediated rejection of intestinal allograft. Humoral rejection is characterized by a grossly cyanotic small intestine allograft. Histologic findings include severe congestion, neutrophilic margination, and fibrin-platelet thrombi within the lamina propria microvasculature, along with focal hemorrhage. Immunohistochemical staining to C4d confirms the diagnosis of antibody-mediated rejection with heavy and diffuse staining of the lamina propria capillaries.

of allograft and loss of previous intestinal allograft. The clinical presentation of chronic rejection may include weight loss, chronic diarrhea, intermittent fevers, recurrent subacute bowel obstruction and distal intestinal allograft obstruction, or GI bleeding. Histologically, chronic rejection is characterized by villous blunting, focal ulcerations, epithelial metaplasia, and scant cellular infiltrates on endoscopic mucosal biopsies but can be difficult to diagnose based on just a mucosal biopsy as larger vessels need to be ascertained. Full-thickness biopsies of intestinal allografts with chronic rejection demonstrate the classical obliterative thickening of not only intestinal arterioles but also even bigger vessels.

■ MANAGEMENT OF COMPLICATIONS

Postoperative Hemorrhage

Recipients of intestinal and multivisceral transplants will commonly demonstrate varying degrees of liver dysfunction, qualitative and quantitative platelet abnormalities, and fibrinolysis that can lead to profound intraoperative coagulopathy. Induction intraoperatively with thymoglobulin may also lead to hematologic and clotting diathesis and warrant cessation or slowing down/delay of the infusion. Intraoperative bleeding can also develop from lysis of vascularized adhesions due to previous surgeries and portal hypertension. Transient graft reperfusion coagulopathy mediated by plasminogen activators from the graft may also occur. Every effort is made to address these factors in the operating room, and usually whatever coagulopathy persists postoperatively is mild. Postoperative hemorrhage is most often a technical problem arising from vascular anastomoses or extensive raw peritoneal surfaces. Even mild coagulopathy should be completely corrected if bleeding is suspected in the posttransplant recipients although caution has to be taken to avoid issues with thrombosis of the allograft. Any bleeding that causes hemodynamic alteration should be managed by early exploration.

Vascular Complications

Superior mesenteric artery thrombosis is a catastrophic complication that leads to rapid and massive necrosis of the intestinal allograft. Elevation of hepatic enzymes (with liver allografts) and pallor of the intestinal stoma are accompanied by clinical deterioration, usually fulminant sepsis, and hepatic coma (with liver allografts). Isolated small bowel allografts can be explanted with a reasonable expectation of patient survival, but in patients with composite allografts removal for arterial thrombosis leads to almost certain death in the absence of immediate retransplant. Clinical suspicion of arterial thrombosis in the immediate postoperative period should be definitively evaluated in the operating room and not delayed by performance of Doppler ultrasound examination. In cases of delayed presentation, arteriography in interventional radiology can often be useful diagnostically and therapeutically.

Acute venous thrombosis also leads to loss of the intestinal allograft without timely surgical intervention. Clinical signs of venous thrombosis include acute massive ascites and stomal congestion. Mesenteric infarction is the ultimate outcome of unresolved venous thrombosis, necessitating explant of the intestinal allograft.

Incomplete obstruction of major inflow or outflow vessels may be suspected based on allograft biopsies or on clinical and laboratory signs of graft dysfunction. Contrast vascular radiographic studies are confirmatory, and the correction is either surgical or endovascular based upon individual assessments and available clinical expertise.

Gastrointestinal Complications

Gastrointestinal bleeding after intestinal transplantation is an ominous sign that requires timely evaluation. Acute rejection and infectious enteritis are the most likely etiologies and should be diagnosed or excluded based upon endoscopic biopsy results, although arterioenteric fistulae must also be considered, as this can be catastrophic. The

FIGURE 160-12 ■ Chronic rejection of intestinal allograft. Mucosa shows loss of villous architecture, chronic ulcers with exudate and granulation tissue, widespread loss of the crypts of Lieberkühn, crypts of Lieberkühn with pyloric gland metaplasia (**A**, arrow), neuronal hyperplasia (**B**, arrow) and mucosal fibrosis. Histologic findings in resection specimens are obliterative arteriopathy (**C**), lymphoid deletion, and mesenteric sclerosis (**D**).

diagnosis of rejection relies primarily on histologic evidence but also on the endoscopic appearance of the mucosa. Bleeding from ulcerated EBV- or CMV-induced lesions may be differentiated by gross endoscopic examination, but confirmatory stains and serum PCR testing often help validate the diagnosis. Empiric therapy for rejection of intestinal allografts is rarely indicated except when suspicion on clinical and/or endoscopic evaluation is high and infectious parameters have been low and obtaining pathologic confirmation is delayed.

Anastomotic leaks may occur in all intestinal transplant recipients but are more common in pediatric patients. Clinical presentation commonly involves florid sepsis, drainage via abdominal drain, or wound drainage and infection. Confirmation is achieved with oral contrast imaging. Owing to immunosuppression, almost all bowel leaks require surgical revision, evacuation of any peritoneal contamination, and often second-look laparotomy to confirm resolution. Diagnostic laparotomy is indicated in the setting of sepsis and equivocal imaging studies.

The progression of motility patterns in the denervated intestinal allograft is still not fully understood. High allograft stomal output occurs early after transplant, and in the absence of infection or rejection, it can be regulated with agents such as loperamide, lomotil, pargoric, or pectin. Conversely, often poor upper motility may exist between the native and allograft bowel, and promotility agents may be required.

Renal Complications

Deterioration of renal function in intestinal transplant recipients remains a significant clinical challenge. Pretransplant renal dysfunc-

tion is exacerbated by overall higher target levels of immunosuppression in intestinal transplant recipients compared to other types of transplants, as well as repeated exposure to nephrotoxic antibiotics, and episodes of dehydration with intestinal allograft dysfunction. The incidence of chronic renal failure for intestinal transplant recipients at 5 years post transplant exceeds 15%.³⁴ Overall, a review of the Scientific Registry of Transplant Recipients (SRTTR) data shows that patients without severe pretransplant renal dysfunction who do not receive a kidney as part of the composite allograft will generally demonstrate a 50% increase in serum creatinine at their 5-year follow-up.

Posttransplant Lymphoproliferative Disorder

The development of PTLD is almost always associated with EBV infection. Posttransplant infection with EBV results in a spectrum of diseases, from mononucleosis syndromes and plasma cell hyperplasia to neoplastic PTLD (Fig. 160-13). In a series of 500 intestinal and multivisceral transplants at the University of Pittsburgh, all but two of 57 recipients with PTLD developed the disorder as a consequence of confirmed EBV infection. Early studies found that primary tacrolimus use in pediatric patients was associated with a 15% long-term risk of PTLD, with almost 80% of these cases occurring within the first 2 years after transplant. Achieving an optimal immunosuppression steady state and avoiding excessive therapy intervals appears to be key to minimizing EBV/PTLD complications. Cumulative PTLD-free survival for intestinal transplant recipients undergoing induction immunosuppression has improved to nearly 90%, possibly attributable to a lower incidence of acute rejection (and thus decreased need for escalation of immunosuppression) as well as improved EBV viral load monitoring.

FIGURE 160-13 ■ Epstein-Barr virus posttransplant lymphoproliferative disorder (EBV/PTLD). At the early phase of EBV infection, tissue is expanded by scattered EBV encapsulated RNA (EBER)-positive lymphocytes. With disease progression, the number of positive cells increases, lymphocytes become activated and transformed, and ultimately, tissue architecture is effaced by a malignant lymphoproliferative process that replaces the duodenal mucosa seen in this example. The EBER in situ probe is shown in the inset.

Patients presenting with PTLD complain of sporadic fever, lethargy, and malaise. Weight loss, diarrhea, and GI complaints are common, as are signs of graft dysfunction. Standard laboratory evaluation may demonstrate neutropenia, atypical lymphocytosis, anemia, and thrombocytopenia. Further evaluation of PTLD is guided by findings on contrast-enhanced computed tomography (CT) scanning of the head, neck, chest, abdomen, and pelvis, with or without endoscopy, based on results of noninvasive imaging. Histologic examination of the tissue is optimal, and specimens should be promptly submitted for fresh staining with the EBER-1 probe by experienced pathologists. An evaluation for CD20 staining should also be performed.

Ideally, the treatment of PTLD involves stopping immunosuppression completely, as can be done in most other types of allografts, but with the intestine this may not be possible. The goal, however, is to lower the level of immunosuppression as much as possible (holding steroids and third agents and lower primary agent) and follow very closely with repeat scopes and biopsies. PTLD that is unresponsive to lowering/discontinuation of immunosuppression should be treated with monoclonal antibody, usually rituximab, if shown to be CD20 positive by biopsy. Complete remission rates of 60% to 70% have been reported in children. The antibody therapy is relatively well tolerated, and for the 20% of patients who have recurrence, retreatment with rituximab can be curative. For PTLD refractory to monoclonal antibody, low-dose cytotoxic chemotherapy and steroids have been used effectively (Gross protocol).

Graft-Versus-Host Disease

Acute graft-versus-host disease (GVHD) results from immunocompetent donor T cells causing damage to recipient tissues after transplantation. The incidence of GVHD (Fig. 160-14) after intestinal transplantation ranges between 5% and 10% and usually occurs within the first 6 months post transplant.³⁵ The major targets of GVHD intestinal transplant recipients are epithelial cells of skin, bone marrow, the native GI tract and the native liver. Cardiac muscle involvement is not common but has been described. A recipient with GVHD commonly presents with fever and a maculopapular rash on the upper

FIGURE 160-14 ■ Intestinal allograft graft-versus-host disease (GVHD). Mucosal biopsy of native small intestine showing crypt epithelial apoptosis and lamina propria inflammation. An incidental CMV inclusion is also noted in this biopsy (arrow).

torso, neck, or palms of hands and feet, which may coalesce to form blisters or more diffuse erythema. Other clinical signs and symptoms include oral lesions, diarrhea, intestinal mucosal ulceration, native liver dysfunction, lymphadenopathy,³⁶ and bone marrow suppression with pancytopenia. The variability of GVHD focality and severity leads to a wide spectrum of disease, from mild GVHD presenting with fevers and self-limiting rash to more severe forms leading to end-organ damage.

The diagnosis of GVHD is based on clinical presentation and confirmed histologically, when possible. Corticosteroids are the first-line therapy to control epithelial damage caused by GVHD and are effective in around 50% of the cases, overall. If unresponsive to steroids, GVHD can usually be controlled by reduction of calcineurin-based immunosuppression, although in some cases the level of immunosuppression needs to be augmented. Other forms of refractory GVHD have been treated successfully using antilymphocytic therapy (e.g., Thymoglobulin), as well as antiinterleukin therapy (e.g., Zenapax and Simulect) and anti-tumor necrosis factor (TNF) antibody therapy (e.g., Remicade).

OUTCOMES

Patient and Graft Survival

From January 1985 to January 2015, according to the latest update of the Intestinal Transplant Registry, there have been 3067 intestinal transplants performed in 84 centers around the world, with 30 centers still currently active. Small bowel transplants alone account for 45% of the total, liver/intestine 31%, and multivisceral/modified multivisceral the remainder. Currently there are 1631 survivors. The leading cause of recipient death is sepsis (65%), followed by graft failure (10%), lymphoma (5%), technical issues (4%), and then cardiovascular, renal, and liver failure. The retransplantation rate is approximately 10%, with most being liver inclusive.

A significant improvement in early patient and graft survival after intestinal transplantation has been achieved over the past decade and a half, with 1-year patient and graft survival (Fig. 160-15) reaching 89% and 79% for intestine-only recipients and 72% and 69% for liver-intestine recipients, respectively. In 1998, the 1-year adjusted graft and patient survival after intestinal transplantation were only 52% and 69%, respectively. Data from the Children's Hospital of Pittsburgh on 262 intestinal transplants between 1990 and 2015 show 1- and 5-year survival of 84% and 63%, respectively, with about half the recipients currently alive. Survival of both patient and graft has improved over

FIGURE 160-15 ■ Unadjusted patient and graft survival for isolated intestine and combined liver and intestine recipients. (Adapted from Mazariegos GV, Steffick DE, Horslen S, et al. Intestine transplantation in the United States, 1999–2008. *Am J Transplant* 2010;10:1020–1034.)

time for multifactorial reasons, with the most recent patients undergoing Thymoglobulin induction doing the best.

Updated outcomes for intestinal transplant recipients are now comparable to outcomes following pancreas and lung transplantation. Contributing factors to this marked improvement in outcomes after intestinal transplantation include increased experience among intestinal transplant teams, improvements in anesthesia and critical care, advances in immunosuppression, and advances in the detection and treatment of rejection. The hospitalization status of the recipient at the time of transplantation also remains a strongly predictive factor for patient survival, with an unadjusted 1-year survival rate of 83% for recipients not waiting in the hospital, 73% for recipients waiting in the hospital, and only 50% for recipients waiting in the ICU. In 1999, almost one-third of intestinal and multivisceral recipients were in intensive care at the time of transplantation, whereas in 2008, 70% were not in the hospital, and only 12% were in intensive care.

In contrast to recent achievements in short-term outcomes, long-term survival after isolated intestinal transplantation has not significantly improved. Ten-year patient and graft survival remains 46% and 29%, respectively, for isolated intestinal transplantation and 42% and 39%, respectively, for intestine-with-liver grafts. These results are similar to those reported for lung and combined heart-lung transplantation but compare unfavorably to kidney, liver, and heart transplantations, where 10-year patient and graft survival exceeds 50%.

The conclusion from the most recent Intestine Transplant Registry is that there have been no major advances in intestinal transplant graft survival rates for the past 5 years. Short-term outcomes are excellent, but longer term outcomes remain suboptimal. Factors associated with a better graft survival include being a pediatric recipient, being called in from home for transplant, having a liver allograft as part of the transplant, and early maintenance of rapamycin (although the last finding is being reanalyzed because of supporting evidence).

Long-Term Rehabilitation and Quality of Life

There are only a few reports pertaining to long-term outcomes, especially pertaining to quality of life, partly as the field is still relatively new and only a few centers have significant numbers to make a useful assessment. A small preliminary study³⁷ in pediatric recipients with functioning intestinal allografts more than 1 year post transplant found that quality of life was perceived by recipients to be comparable to that of their peers, while parental proxy assessments compared less favorably in terms of physical functioning, general health, and family

activities. Younger recipients (5–10 years of age) demonstrated significantly worse outcomes than older recipients (11–18 years of age) in terms of global health assessments, general health perception, and family activities. There have been reports demonstrating significant improvement in certain aspects of psychiatric health after transition from PN to posttransplant PN independence.³⁸ In these reports, long-term physical and psychiatric rehabilitation was achieved in over 80% of intestinal transplant recipients who survived beyond the sixth postoperative month.

The most robust recent paper details 227 adult and pediatric recipients who survived beyond the 5-year milestone.³⁹ Conditional survival was 75% at 10 years and 61% at 15 years. Nutritional autonomy was achieved in 90% of the survivors. Morbidities with impact on global health included dysmotility (59%), hypertension (37%), osteoporosis (22%), and diabetes (11%) and were observed more in the adult population. Survivors in general were reintegrated into society with self-sustained socioeconomic states. It is also vital to note that nonfunctional social support was one of the most significant survival risk factors. This evidence ties back to the original evaluation process, and the importance of teaching and assessing social support. No matter how good the medical, surgical, and transplant management may be, for continued long-term success adequate and appropriate social resources are essential. The intestinal and multivisceral transplant process is demanding and forever ongoing for the recipient, the family, and the healthcare professional team. Hence, picking the right recipient for transplantation is vital and conversely one of the reasons why all efforts are made to rehabilitate patients without transplantation, if at all possible, given these long-term concerns.

CONCLUSION

The field of intestinal failure has undergone ebbs and flows, based on medical, surgical, and transplantation advances and outcomes. Intestinal and multivisceral transplantation remains the ultimate therapy, but with improved medical and surgical management the timing and utility of transplantation have shifted.

Significant improvements in outcomes from intestinal and multivisceral transplantation have been achieved through advances in the multidisciplinary care of intestinal failure, surgical techniques, innovative immunosuppressive strategies, and an improved understanding of intestinal transplantation immunology. These accomplishments, however, remain overshadowed by the remaining fundamental challenge of preventing or minimizing chronic allograft rejections. The

relatively high waiting list mortality, particularly for infants and adults with concomitant liver failure, requires an ongoing reexamination of national guidelines for multivisceral procurement to maximize the usage of acceptable donor allografts. Limited long-term data on nutritional outcomes and transplantation morbidity indicate good allograft survival and quality of life for those who get through the early period, however, not without some significant morbidity. Once again, ongoing continual loss of the nonliver-containing intestinal allograft hampers wider acceptance of intestinal transplantation failure. More so, the

recent dramatic improvements in the provision of exemplary care in the multidisciplinary intestinal care clinics have significantly altered the need, timing and type of intestinal allograft needed. With no substantial advancement in the field of intestinal transplantation over the past decade, the pendulum of transplantation versus delaying/avoiding transplantation has swung once again. Still intestinal transplantation, until successful tissue engineering evolves or some other new modality of treatment is developed, remains the ultimate and definitive form of intestinal failure salvage.

Aortic dissection remains a highly lethal condition, and the incidence may be on the rise.¹ Diagnosis remains difficult, and over one-third of the cases are missed at initial presentation.² In the absence of treatment, patients die at a rate of 1% to 2% per hour during the first 24 hours, and nearly 50% die within 1 week.^{3,4} Herein, we will discuss the optimal diagnostic and treatment strategies for thoracic aortic dissection including preoperative, operative, and postoperative care.

DEFINITION AND EPIDEMIOLOGY

The aorta is comprised of three layers, the endothelial-lined intima, the media composed of muscular and connective tissues, and the adventitia. When the intimal layer is disrupted, blood ejected under pressure enters the medial layer, thereby creating two lumens in the aorta—an aortic dissection. The true lumen can become compressed or even obliterated by the false lumen. The dissection can propagate proximally (retrograde) toward the aortic valve or distally (antegrade). Morbidity and mortality occur due to a host of complications. The disruption of myocardial blood flow from coronary ostial involvement can result in myocardial infarction, acute heart failure can occur from acute aortic valve regurgitation due to commissural dehiscence, and pericardial tamponade can develop from bleeding into the pericardial space. Aortic dissection can compromise blood flow through almost any major artery, resulting in stroke, spinal ischemia/paralysis, mesenteric ischemia, renal failure, or limb ischemia. Aortic rupture can occur, leading to catastrophic hemorrhage.

The incidence of acute aortic dissection ranges from 3 to 6 per 100,000/yr.^{1,5} There is a male predominance, with a male:female ratio ranging from 2 to 3:1.⁶ The mean age of presentation is 63 years (range 50–63). The majority of aortic dissections involve the ascending aorta (70%–80%), whereas the remaining 20% to 30% involve the descending thoracic aorta and less frequently the aortic arch.

CLASSIFICATION

Classification Systems: DeBakey and Stanford

The two most widely used classification systems for aortic dissection are the DeBakey and Stanford (Fig. 161-1). DeBakey and colleagues developed the first widely used classification system for categorizing aortic dissections.⁷ It divides dissections into types I, II, and III based on the site of the originating tear. A DeBakey type I dissection originates in the ascending aorta and extends through the descending thoracic aorta. A type II dissection involves only the ascending aorta. The tear in a type III dissection originates in the descending thoracic aorta distal to the ligamentum arteriosum. The DeBakey type III dissections are further subdivided into IIIA, originating distal to the left subclavian artery and extending to the diaphragm, and IIIB, involving the aorta below the diaphragm. The Stanford classification system reported by Daily and colleagues⁸ divides dissections into two groups: Stanford type A aortic dissections, involving the ascending aorta, and type B dissections, “limited to the descending aorta with primary intimal tear usually within 2 to 5 cm of the left subclavian artery.”⁸ This is a key area of importance, as there is controversy regarding classification and management of arch aneurysms. On the basis of the

initial description of the Stanford system, many consider dissections involving the aortic arch without ascending involvement to be type B dissections.

The aforementioned classification systems provide a framework for managing patients with aortic dissection. We use the Stanford system, as it provides a simple approach for separating patients who should be considered for immediate surgery versus medical management. The primary lethality of dissection results from coronary ostial involvement and subsequent myocardial infarction, severe aortic valve insufficiency from commissural detachment, or pericardial tamponade, all of which can occur in the setting of ascending aortic involvement or type A dissections. Although complications involving the abdominal viscera can occur with type B dissections, these are not as common. Therefore, speaking in broad terms, type A aortic dissections are managed with surgery and type B medically (unless they are complicated by bleeding or malperfusion).

In addition to determining the dissection type (A vs. B, I vs. II vs. III), dividing dissections based on duration from symptom onset is essential for management, as chronic dissections can be managed on a more elective basis. Traditionally, dissections are termed *acute* if symptoms have been present for less than 2 weeks and *chronic* if present for greater than 2 weeks. Booher and colleagues have developed a new classification system that classifies dissections as hyperacute (<24 hours from symptom onset), acute (2–7 days), subacute (8–30 days), and chronic (>30 days), as survival differs significantly by category.⁹

PRESENTATION

History and Risk Factors

The most typical complaint at presentation in patients with aortic dissection is abrupt and severe chest pain, followed by back pain. Classically described as tearing, the pain can also be sharp, ripping, or knife-like. Some degree of chest pain is present in three-fourths of patients, followed by back pain in 40% and abdominal pain in 25%.^{3,10,11} Ten percent of patients may present with no complaints of pain at all.² Additional neurologic complaints may include syncope, complaints of weakness or paresis, or rarely hoarseness from left recurrent laryngeal nerve compression. Abdominal pain may be the result of pain from the dissection itself or mesenteric ischemia. Key elements of the history that should be queried in the setting of chest or back pain and should raise the index of suspicion for aortic dissection are outlined in Box 161-1.

Physical Examination

Physical examination may not be diagnostic but in conjunction with the history, can aid in raising the suspicion for acute aortic dissection. Tachycardia may occur due to pain or hypovolemia if rupture has occurred. Bradycardia or heart block may occur with root involvement of the dissection. Blood pressure measurements should be taken in both arms, and a 20-mm Hg differential should raise the suspicion for dissection. Neurologic examination should assess the overall mental status and for findings of stroke or spinal cord ischemia. Paresthesias and motor deficits may be seen in the absence of stroke when arterial insufficiency and limb ischemia are present. Absent breath sounds in

FIGURE 161-1 ■ Schematic illustration of Stanford classification system of aortic dissections. Examples in the top row (**A, B, C**) are all type A aortic dissections involving the ascending aorta. Examples in the bottom row (**D, E, F**) are all examples of type B dissections in which the ascending aorta is not involved. Note that the aortic arch can be involved in a type B dissection. GENETIC/HEREDITARY/CONGENITAL CONDITIONS

Marfan syndrome
 Loeys-Dietz syndrome
 Ehlers-Danlos syndrome
 Turner's syndrome
 Bicuspid aortic valve
 Familial thoracic aortic aneurysm/dissection syndrome
 Aortic coarctation

INFLAMMATORY/AUTOIMMUNE CONDITIONS

Takayasu arteritis
 Giant cell arteritis
 Syphilitic aortitis

ACQUIRED CONDITIONS

Hypertension
 Smoking
 Cocaine
 Amphetamines
 Pregnancy
 Trauma
 Postprocedural
 Cardiac catheterization
 Intraaortic balloon pump placement
 Cardiac surgery

the left hemithorax can be seen with rupture. Cardiac examination should focus on the presence of an early diastolic murmur with a loud P2 component as seen with acute aortic regurgitation. Muffled heart sounds in conjunction with hypotension should alert for tamponade and the presence of a type A dissection. A thorough pulse examination is essential, as acute limb ischemia will not be seen in the setting of

other causes of chest pain such as pulmonary embolism. Abdominal tenderness should raise a concern for the involvement of the descending thoracic or abdominal aorta and the possibility of mesenteric ischemia. Examination of the extremities should assess for ischemia and also for the presence of connective tissue disorders such as Marfan syndrome.^{11,14}

■ DIAGNOSTIC TESTING

Laboratory Testing and Electrocardiogram

Routine laboratory analysis is generally unhelpful in diagnosing aortic dissection. Standard complete blood count may demonstrate anemia if there has been significant blood loss as in the case of dissection complicated by rupture. Chemistry panels may demonstrate low serum bicarbonate or elevated lactic acid levels if hypotension has been present for a prolonged duration with systemic hypoperfusion. Significantly elevated lactic acid levels should raise concern for compromise of perfusion to the abdominal viscera, particularly compromise of the mesenteric circulation to the bowel, which is ominous in terms of survival. Cardiac enzymes (creatinine kinase [CK], CK-myocardial band, and troponin) may be elevated in the setting of demand ischemia or if there is involvement of the aortic root and compromise of the coronary ostia. Extensive investigation has been performed to identify blood markers of dissection to aid in early diagnosis, but at this time, no sole lab value or combination of values is in routine clinical use for diagnosis. Testing for D-dimer, soluble elastin fragments, and smooth muscle myosin heavy chain have thus far yielded the most promising results, but none is routinely used in the clinical setting.¹⁵⁻²⁰

Electrocardiograms (ECGs/EKGs) should be obtained in all patients presenting with chest pain or concern for aortic dissection. Acute EKG changes can be present in nearly half of the patients and chronic changes in one-third of the patients. ST elevation is often associated with coronary ostial involvement of the dissection flap. These findings should be taken into particular consideration prior to initiating systemic anticoagulation or thrombolytics, which may be catastrophic in the setting of acute aortic dissection.²¹

Imaging

Historically, invasive angiography has been used but has since been replaced with echocardiography, computed tomography (CT), and magnetic resonance imaging (MRI). For diagnosis, whichever modality is used will need to visualize a dissection flap within the aorta and visualize the site of the entry tear. Additional information will aid in management.

Standard chest radiograph (CXR) findings are neither sensitive nor specific for diagnosing aortic dissection but can be useful to identify other diagnoses and raise an index of suspicion for dissection. A widened mediastinum is present in 62% of the cases, and a blunted aortic knob may be seen. Additional findings suggestive of intrathoracic dissection include an irregular or double aortic contour or inward displacement of atherosclerotic calcification. The presence of a large left pleural effusion should raise concern for hemothorax. The CXR may be normal in 10% to 15% of patients.³

Contrast-enhanced CT scanning is the most widely used. Ideally a contrast-enhanced study should be obtained. If dissection is suspected before the imaging, imaging should be obtained from the base of the neck through the pelvis to delineate the extent of dissection and distal involvement. Helical scanning and ECG gating limit motion artifact and have been shown to have sensitivity and specificity rates of 95% to 98%.²² Contrast-enhanced CT imaging allows for distinction between type A and type B aortic dissections and allows for surgical planning (Figs. 161-2 and 161-3). Limitations of CT scanning include motion artifact in patients who are unable to remain still during image acquisition, the need for iodinated contrast dye, and the use of ionizing radiation.²³

FIGURE 161-2 ■ Acute type A aortic dissection. Axial (A) and coronal (B) views.

FIGURE 161-3 ■ Acute type B aortic dissection. Axial (A) and coronal (B) views.

Magnetic resonance imaging/angiography is not widely used for diagnosing dissection because of limited availability and the time required for image acquisition relative to CT scanning. From an imaging perspective, MR imaging provides the best sensitivity and diagnostic odds ratio relative to CT or transesophageal echocardiography (TEE) with sensitivity and specificity rates greater than 98%, and is the best imaging modality to confirm the presence of dissection if other imaging is equivocal.²⁴

Coronary angiography is rarely performed unless there is clear compromise of myocardial perfusion. Coronary angiography may delay definitive treatment and rarely improves the management. However, when the patient has a clear history of coronary artery disease and is hemodynamically stable, consideration may be given to performing coronary angiography if the patient presents with a *chronic* type A aortic dissection.

Transthoracic echocardiography (TTE) can be useful for diagnosing aortic dissection but is limited primarily by poor sensitivity. TTE images, which can be obtained rapidly at the bedside in an unstable patient, have the advantage of being noninvasive and the ability to identify aortic valve insufficiency, pericardial effusion or tamponade, and presence of a dissection flap in the ascending aorta or root. The significant limitations of TTE include limited diagnostic accuracy (80% sensitivity and 90% specificity if dissection involves ascending aorta) and difficulty imaging the ascending aorta and arch. Ranges for TTE sensitivity have been reported anywhere between 78% and 100% for diagnosing type A aortic dissection and 31% and 55% for type B aortic dissections.^{22,25}

TEE is significantly more sensitive and specific than TTE but has the limitation of being an invasive procedure, which can have complications such as aspiration, arrhythmia, or esophageal injury. The proximity of the aorta to the esophagus allows for excellent diagnostic accuracy for types A and type B dissections when TEE is used, but depending on the patient's anatomy, visualization of the distal ascending aorta or proximal arch may be limited as a result of air within the trachea or bronchus. Sensitivity of TEE has been reported between 97% and 99%, with specificity rates of 97% and 100%.^{22,26}

For patients who are transferred from a referring institution with an aortic pathology as the diagnosis, reconfirmation of the diagnosis must be performed. Imaging studies should be requested with the transfer of the patient for review and to avoid repeating studies. A study by Beaver and colleagues reviewed a series of patients transferred to their tertiary care center with a referring diagnosis of aortic dissection or aneurysm. Approximately 25% of the referring diagnoses were incorrect. Most commonly, aortic dissections were misdiagnosed as aortic aneurysms or aneurysms as dissections. Less frequently, the dissection type (A vs. B) was incorrect, or there was no aortic

pathology present at all.²⁷ Given the differences in the management for aneurysms versus dissections and types of dissections, personal image review is essential.

MEDICAL MANAGEMENT OF TYPE A AND TYPE B AORTIC DISSECTIONS

Once the diagnosis has been established, care should immediately focus on blood pressure management and need for surgical intervention.^{28,29} Sufficient intravenous access should be obtained with central venous line placement for administering vasoactive drugs. Arterial blood pressure should be monitored with an arterial line placed preferably in the radial artery, as the femoral artery may be needed for cannulation during surgery or may be involved in the dissection. Care should be taken when selecting the site of arterial catheterization based on the extent of dissection, as when there is subclavian arterial involvement, blood pressure readings may be artificially low because of compromised flow in the true lumen. Pain should be aggressively controlled with narcotics as necessary and during any procedures such as line placement to avoid sudden exacerbation of hypertension and to minimize endogenous catecholamine release from discomfort and anxiety. The primary tenet of medical management centers on anti-impulse therapy, which aims to limit propagation of the dissection by reducing the change in pressure over the change in time (dp/dt). If the patient is hypertensive, the initial treatment of choice is intravenous beta-blockade if the heart rate allows. Labetalol, esmolol, and metoprolol are all reasonable choices with doses as outlined in Table 161-1. If the heart rate is less than 70 at baseline or the blood pressure remains greater than 120 mm Hg systolic after the initiation of beta-blockers, afterload reduction with vasodilators such as sodium nitroprusside or nicardipine should be initiated. Pure vasodilators should be avoided as the initial treatment, as reflex tachycardia and increased cardiac contractility may increase dp/dt and theoretically propagate the dissection. Goal heart rates should be between 60 and 70 beats/min with goal systolic blood pressure between 100 and 120 mm Hg.³⁰ If pericardial tamponade is present or develops, pericardiocentesis should be avoided because there are high rates of cardiac arrest postprocedurally when performed in the setting of dissection.³¹ These events may occur due to abrupt increases in blood pressure after release of intrapericardial pressure with subsequent exacerbation of hemorrhage. If tamponade is encountered, aggressive volume resuscitation should be undertaken to optimize intracardiac filling, and definitive drainage can occur during surgery.

Patients may present with a range of neurologic deficits ranging from paresthesias to stroke. In patients with a delayed diagnosis and completion of a significant stroke, the use of high doses of heparin required for cardiopulmonary bypass and the restoration of blood flow to the brain may result in intracranial hemorrhage or catastrophic cerebral edema. Preoperative CT scanning of the brain may aid in determining the extent and severity of infarction. In patients present-

ing with recent onset of stroke, stroke-like symptoms, or fluctuating neurologic exam, surgical outcomes are acceptable provided restoration of perfusion to the brain can be obtained with dissection repair.³² Advanced age above 80 years remains an area of debate. Rates of mortality for emergency surgery for type A dissection in patients aged 80 years and older have been reported at nearly 50% to 60%, and survival with a nonoperative approach may be similar in patients beyond the age of 80 years.³³⁻³⁵ Decision to operate on patients older than 80 years remains at the surgeon's discretion, as reasonable survival may be obtained in these patients with medical management.³⁶ In addition to patients presenting with extensive stroke or advanced age, those with underlying comorbidities such as advanced malignancy, cirrhosis, or extensive mesenteric ischemia/bowel infarction may not be considered surgical candidates.³⁷ Certain patients may be diagnosed after the acute phase (2 weeks) with a chronic type A aortic dissection. These most commonly will be patients in whom the diagnosis is made incidentally during imaging for other complaints, or those who present weeks after symptom onset. In surviving the acute period, these patients have self-selected for medical management, and indications for surgery in the asymptomatic patient would electively be based on aortic size from aneurysmal change rather than the presence of dissection.

For patients with acute type B aortic dissection that is uncomplicated, medical management as detailed earlier is the primary treatment strategy, with acute surgical intervention reserved for those who present with or develop complications (see "Surgical Management of Type B Aortic Dissection") and possible delayed (weeks to months later) surgical intervention for potentially improved aortic remodeling. Once blood pressure and pain have been normalized for 24 to 48 hours, intravenous medications can be converted to oral agents, and transfer out of the critical care setting is reasonable. Imaging should be obtained prior to discharge with CT scanning or MRI to ensure there has been no progression of dissection and for baseline assessment.

SURGICAL MANAGEMENT OF TYPE A AORTIC DISSECTION

The primary goal of surgery for acute type A aortic dissection is to immediately treat the life-threatening pathology and then to prevent future complications. Thus, the extent of surgical procedure required will take into account the origin of the dissection, involvement of the aortic root/valve, arch and descending aorta, and, importantly, the overall condition of patients, as extensive reconstructions may not be well tolerated in the elderly or patients with major comorbidities or ongoing visceral or extremity ischemia.

Ascending Aortic Replacement

In cases where the dissection is limited to the ascending aorta or the intimal tear is clearly identified in the ascending aorta, aortic replacement with a polyester graft from the level of the sinotubular junction to the distal ascending aorta is performed. If the aortic valve is normal but acute aortic insufficiency has resulted from detachment of the aortic valve commissures, valve competency can be restored by resuspension of the commissural posts. The aortic root and coronary arteries are left in situ. Depending on a patient's anatomy and a surgeon's preference, the operation can be performed without deep hypothermic circulatory arrest.

Ascending Aortic Replacement with Aortic Valve Replacement

Similarly, in cases where the dissection is limited to the ascending aorta or the intimal tear is clearly identified in the ascending aorta, aortic replacement with a polyester graft from the level of the sinotubular junction to the distal ascending aorta is performed. If the aortic valve is incompetent but the coronary ostia are otherwise uninvolved and the sinuses of Valsalva are not aneurysmal, the aortic valve may be

TABLE 161-1 Medical Management for Patients with Acute Aortic Dissection

| DRUG | DOSAGE |
|----------------------|--|
| Labetalol | 0.25 mg/kg IV over 2 minutes; 40-80 mg q 10 min up to 300 mg; 1-2 mg/min IV infusion |
| Esmolol | 50-200 µg/kg per minute IV infusion |
| Metoprolol | 5 mg IV slow bolus up to 4 doses 15 minutes apart |
| Nicardipine | 5-15 mg/h IV infusion |
| Diltiazem | 0.25 mg/kg IV over 2 minutes; 5-10 mg/h IV infusion |
| Sodium nitroprusside | 0.2-0.3 µg/kg per minute up to 300 µg/min IV infusion |

IV, intravenous.

replaced with a tissue or mechanical prosthesis and the remainder of the aortic root left intact. As mentioned earlier, depending on a patient's anatomy and a surgeon's preference, the operation can be performed without deep hypothermic circulatory arrest.

Aortic Root Replacement

When there is extensive destruction of the aortic root, complex reconstruction must be undertaken. In this setting, there is usually extensive coronary ostial involvement, the native aortic valve is unsalvageable, or there is aneurysmal degeneration or destruction of the sinuses of Valsalva. To address the aortic valve, the valve may be replaced with a mechanical prosthesis attached to a polyester aortic graft (Bentall procedure), a tissue prosthesis attached to a polyester aortic graft (bio-Bentall procedure), or the valve leaflets may be preserved and the native valve reconstructed (valve-sparing aortic root replacement or David procedure). In addition to addressing the valve, the sinuses of Valsalva are replaced with the graft conduit, and the native coronary arteries are reimplanted into the graft.

Aortic Hemiarch Replacement

When the dissection extends beyond the distal ascending aorta and the flap or site of intimal tear is visualized in the proximal underside of the aortic arch, hemiarch replacement may be considered. In hemiarch replacement, the ascending aortic graft is beveled, or, alternatively, two separate grafts may be used and the underside of the arch is replaced. The innominate artery, right common carotid, and left subclavian artery are left in situ. This will require deep hypothermic circulatory arrest to provide adequate visualization and the ability to resect an adequate amount of diseased tissue.

Aortic Arch Replacement

If there is extensive dissection involvement of the aortic arch or branch vessels originating from the aortic arch or there is aneurysmal disease of the arch, complete aortic arch replacement is undertaken. Complete reconstruction of the aortic arch requires deep hypothermic circulatory arrest. The diseased aorta is excised or excluded distally to beyond the left subclavian artery. The innominate artery, right common carotid artery, and left subclavian artery are isolated individually, or as an "island" with a common cuff of aortic tissue, and implanted onto the synthetic graft after the graft has been anastomosed distally to the descending thoracic aorta. The proximal portion of the graft is then anastomosed directly to the ascending aortic graft or the sinotubular junction. At times, the left subclavian artery may be sacrificed if reimplantation is not technically feasible. If significant aneurysmal disease exists beyond the left subclavian artery and there is consideration for future open replacement or stent grafting of the descending thoracic aorta, an "elephant trunk" procedure may be performed. In this setting, the synthetic aortic graft is anastomosed distal to the left subclavian artery, but approximately 10 cm of the graft unfolds distally into the descending thoracic aorta. These operations are technically demanding and require extended periods of circulatory arrest, increasing the risk of neurologic complications.

Thoracic Endovascular Aortic Repair

Conventional surgery remains the standard of care for managing acute type A aortic dissection, but as detailed earlier, certain patients may not be operative candidates or tolerate extensive surgery. Thoracic endovascular aortic repair (TEVAR) is an area of active investigation for managing ascending aortic pathology, and early reports indicate future promise for patients without extensive root involvement. The largest series thus far reported on 22 patients undergoing TEVAR of the ascending aorta, 9 of whom had acute type A dissection, 2 with chronic type A dissection, and 2 with intramural hematoma. The early mortality was 13.6%, and major complications were not uncommon.

As development of device technology continues, outcomes should improve.³⁸

SURGICAL MANAGEMENT OF TYPE B AORTIC DISSECTION

Approximately 25% of acute type B aortic dissections will present with or progress to complications that may be an indication for surgical intervention. Indications for intervention in the setting of acute type B dissection include significant visceral or extremity malperfusion, persistent pain, saccular aneurysm, hemothorax, or evidence of impending rupture. In the setting of a chronic type B dissection, primary indications for intervention include recurrent pain, growth, or aneurysmal degeneration. These indications are evolving as surgeons are more aggressively pursuing TEVAR in the absence of complication to improve aortic remodeling.^{39,40}

Descending Thoracic Aortic Replacement

Open replacement of the descending thoracic aorta is approached via a left posterolateral thoracotomy. Single-lung ventilation is used to provide exposure in the operative field. Commonly, partial left heart bypass obtaining drainage from the left atrium with arterial inflow returned to the femoral artery is used. Alternatively, complete cardiopulmonary bypass can be performed via femoral arterial and venous cannulation. As with type A aortic dissection, a primary goal of the operation is to resect the initial entry tear. As this often occurs near the left subclavian artery, deep hypothermic circulatory arrest may be needed to perform the proximal anastomosis. The descending aorta is then replaced with a polyester-based graft with reimplantation of intercostal islands as needed. The distal anastomosis aims to restore continuity of the true lumen and obliterate the false lumen, thereby restoring perfusion distally. Spinal drainage catheters may be placed preoperatively to optimize the spinal perfusion pressure.

Thoracic Endovascular Aortic Repair

TEVAR is the preferred treatment modality for patients requiring intervention on a type B aortic dissection. Its primary goal is to close the entry tear, stabilize the dissected aorta, and prevent later complications by inducing remodeling. It is performed using a catheter-based approach, generally from the femoral arteries, or at times the iliac arteries, to deploy a covered stent graft across the primary dissection tear. Anatomic requirements for safe deployment of a stent graft include a proximal and distal aortic landing zone diameter of less than 40 mm and at least 20 mm of length. In certain cases, severe peripheral vascular disease or arterial tortuosity may preclude, and an endovascular approach and open repair may be required.

POSTOPERATIVE MANAGEMENT

Immediate postoperative care centers on the management of blood pressure, as during preoperative management, and early detection of complications. The critical care provider should be given a detailed report on operative findings, procedure performed, and areas of potential complications for which to be vigilant. Early and serial neurologic assessment is essential to determine if an intraoperative stroke has occurred (may occur with persistent dissection in the carotid artery as a result of particulate or gaseous embolization during or after surgery or as a result of prolonged deep hypothermic circulatory arrest). In the setting of type B dissection repair, spinal cord ischemia may occur with fluctuations in blood pressure and result in paresthesias or paralysis. As noted earlier, spinal drainage catheters for draining cerebrospinal fluid (CSF) may be placed preoperatively to allow for intervention if this occurs. Goal CSF pressures are 10 mm Hg or less and can be manipulated with additional drainage or increasing mean arterial pressure to greater than 90 mm Hg with vasopressors. Nonfocal neurologic deficits such as delirium or impaired cognition

may be encountered, especially with the use of circulatory arrest. Pain control remains essential to minimize hypertension. Extubation can be considered once hemodynamics has been stabilized and bleeding is controlled. From a hemodynamic perspective, blood pressure control remains critical to prevent suture line bleeding and propagation of residual dissection (if present) within the distal aorta. The extremities should be examined for pulses as ischemia may develop from residual distal dissection or persistence of a false lumen. Compartment syndrome can arise from reperfusion and in the sedated patient may be difficult to diagnose as they will not be able to complain of pain or paresthesias. Abdominal examination should focus on distention or tenderness that can develop from reperfusion or persistent ischemia due to residual dissection in the abdominal aorta. Early abdominal duplex ultrasonography should be considered for complex dissections involving the descending thoracic and abdominal aorta to ensure restoration of adequate perfusion to the liver, kidneys, and bowel after more proximal aortic replacement. Malperfusion may warrant endovascular approaches for fenestration of residual dissection flaps. Urine output should be monitored for volume and color. A significant coagulopathy may be present postoperatively from consumption of coagulation factors during cardiopulmonary bypass, hypothermia, and continued endogenous fibrinolysis occurring within the thrombosed false lumen of the dissection. If a mechanical prosthesis has been used to replace the aortic valve, anticoagulation can generally be safely initiated 48 hours postoperatively. We routinely obtain a transthoracic echocardiogram prior to discharge to ensure no significant aortic valve insufficiency (for preserved, resuspended, or repaired valves) or paravalvular leak exists (for replaced valves). A contrast-enhanced CT scan is also obtained prior to discharge to assess the repair, extent of any residual dissection, and for the presence of pseudoaneurysm.

CONCLUSION

As discussed earlier, the optimal management strategy for acute type A aortic dissection is surgical treatment. Medical management of acute type A dissection results in in-hospital mortality rates of nearly 55% to 60%.⁴¹ Despite advances in surgical technique and perioperative care, operative mortality for acute type A dissection ranges from 7% to 36%, and in-hospital mortality is 27%. For patients surviving the initial hospitalization, the 5-year survival rate is 68% and the 10-year survival rate is 52%.^{33,42}

For patients with uncomplicated type B aortic dissection, hospital mortality is 10% with medical management,⁴³ and 5- and 10-year survival rates range between 60% and 80% and 40% and 45%, respectively.⁴⁴⁻⁴⁶ When managed surgically, the in-hospital mortality with open repair is approximately 32%⁴³ and 9% with TEVAR.⁴⁷

KEY POINTS

1. **Definition:** Aortic dissection occurs when there is disruption of the intima of the aorta. When the intimal layer is disrupted, blood ejected under pressure from the left ventricle enters the medial layer, thereby creating two lumens in the aorta. The true lumen, lined by intima, can become compressed or even obliterated by the false lumen in the medial layer. From the site of the initial intimal entry tear, the dissection can propagate proximally (retrograde) toward the aortic valve or distally (antegrade).
2. **Classification:** Aortic dissections are classified using either the DeBakey or the Stanford classification systems. Stanford type A aortic dissections involve the ascending aorta, and type B dissections are defined as those "limited to the descending aorta with primary intimal tear usually within 2 to 5 cm of the left subclavian artery."
3. **Clinical findings:** History and physical examination may raise an index of suspicion for aortic dissection, but imaging is required for diagnosis. History is most often notable for acute onset of chest or back pain. Key exam findings include differential blood pressures among limbs, diastolic murmurs, pulse deficits, and paresthesias.
4. **Diagnosis:** CT angiography is the most widely used and available modality and allows for anatomic classification and operative planning. Magnetic resonance imaging and TEE may be useful in patients unable to undergo CT imaging or in patients in whom the diagnosis remains in question.
5. **Management:** Optimal heart rate and blood pressure control is essential for the immediate management of all acute aortic dissections, regardless of type. Acute type A aortic dissections are generally managed surgically with replacement of the aorta with a synthetic graft. More complex surgical reconstruction may be undertaken depending on the extent of the dissection. Acute type B aortic dissections, when uncomplicated, are generally managed medically with optimal rate and blood pressure control. Complicated acute type B aortic dissections may require surgical intervention, commonly using an endovascular approach.

ANNOTATED REFERENCES

Daily PO, Trueblood HW, Stinson EB, et al. Management of acute aortic dissections. *Ann Thorac Surg* 1970;10:237-247.

The most frequently used classification system for aortic dissections was developed by Daily and associates at Stanford University. This system of classification, now known as the Stanford classification, involves only two groups. Type A dissections involve the ascending aorta, and type B involve the more distal aorta, from the innominate artery to more distal regions.

David TE, Feindel CM. An aortic valve-sparing operation for patients with aortic incompetence and aneurysm of the ascending aorta. *J Thorac Cardiovasc Surg* 1992;103:617-621.

This paper discusses treatment of aortic dissection involving the aortic root. If the aortic root is severely damaged by the dissection process, the patient has Marfan syndrome or another connective tissue disorder, or severe annuloaortic ectasia is present, or the valve has to be replaced for other reasons (e.g., aortic stenosis). A valve-sparing technique may be appropriate.

Gillinov AM, Lytle BW, Kaplon RJ, et al. Dissection of the ascending aorta after previous cardiac surgery: differences in presentation and management. *J Thorac Cardiovasc Surg* 1999;117:252-260.

The risk of perioperative and late postoperative dissection is discussed in this paper, as well as many other associated pathologic findings such as bicuspid aortic valve, aortic coarctation, and Turner's syndrome. Aortic dissection as a rare complication of cardiac catheterization and other percutaneous diagnostic and therapeutic interventional techniques are also examined.

Miller DC. Surgical management of aortic dissections: indications, perioperative management, and long-term results. In: Doroghazi RM, Slater EE, editors. *Aortic dissection*. New York: McGraw-Hill; 1983. p. 193-243.

This chapter provides an excellent overview of the clinical features, surgical and medical management, and outcomes after aortic dissection.

Most stenoses in the splanchnic vessels remain asymptomatic, but some cause symptoms, and catastrophic complications can develop. Furthermore, there is much confusion regarding the terminology for describing these stenoses. In this chapter, we have used “splanchnic ischemia,” but for all practical purposes the terms *splanchnic ischemia* and *mesenteric ischemia* are interchangeable. This chapter conveys three main messages. First, gastrointestinal (GI) ischemia is an underestimated disorder that may have grave implications in patients. Second, nonocclusive mesenteric ischemia (NOMI) is a common phenomenon in patients in the intensive care unit (ICU), and its diagnosis can prevent overfeeding, provide improved treatment, and achieve better outcomes. Third, the conventional approach for treating bowel infarction (i.e., bowel resection, followed by revascularization) has been replaced by an approach involving endovascular revascularization, followed by inspection of bowel viability and resection of irreversible damage.

PHYSIOLOGY, ANATOMY, AND PATHOPHYSIOLOGY

The Main Vessels: Celiac Artery, Superior Mesenteric Artery, and Inferior Mesenteric Artery

Blood is supplied to the GI tract by three arteries, namely, the celiac artery (CA), superior mesenteric artery (SMA), and inferior mesenteric artery (IMA). Large anatomic variations exist in these vessels. The CA supplies blood to the stomach, the liver, a part of the pancreas, and the proximal part of the duodenum. The SMA supplies blood to the distal part of the duodenum, entire small bowel, ascending colon, and proximal part of the transverse colon. The IMA supplies blood to the distal colon. Branches of these arteries enter the bowel wall to form two plexuses within the serosa and submucosa. Arterioles penetrate the muscular layer toward the mucosa and branch into an extensive network of capillaries and venules that allow the diffusional shunting of oxygen through a countercurrent mechanism. Several collaterals may exist, including Buhler's arc between the CA and SMA and Riolan's artery between the SMA and IMA. The superficial mucosal layer of the bowel is the most susceptible to ischemia because of its high metabolic demand¹ and countercurrent arteriovenous exchange of oxygen.² Blood from the bowel enters the mesenteric veins and finally into the portal vein. The liver receives blood supply from two sources: (1) the portal vein, which provides venous blood, and (2) the hepatic artery, which provides arterial blood. This dual blood supply protects the liver from ischemia.

Regulation of Blood Flow

During fasting, 20% of the cardiac output passes through the splanchnic vasculature. Blood flow doubles after a meal and decreases with an increase in systemic circulatory demands like exercise and shock.

The three main vasoconstrictors are catecholamines, angiotensin II, and endothelin. Catecholamines exert different effects on splanchnic blood flow. Stimulation of α -1 adrenergic receptors leads to vasoconstriction, whereas that of β -2 adrenergic receptors leads to

vasodilatation. Angiotensin II is a key splanchnic vasoconstrictor during low blood flow.³ The main splanchnic vasoconstrictor is endothelin-1.^{4,5} Endothelin-1 activation induces long-lasting vasoconstriction and plays an important and early role in mediating the effects of shock on the integrity of the GI tract.⁶

The main splanchnic vasodilators are nitric oxide (NO) and prostaglandins. Under normal conditions, the endothelium produces NO to sustain perfusion by promoting local vasodilatation. Locally formed prostaglandins act as mucosal vasodilators, especially during low blood flow or after a mucosal injury. Inhibition of cyclooxygenase by nonsteroidal antiinflammatory drugs (NSAIDs) decreases this vasodilatory response and increases the susceptibility of the GI mucosa to the effects of circulatory shock.⁷

Low Flow Conditions

All the previously mentioned receptors and messengers act to balance perfusion with metabolic demands on a moment-to-moment basis. When circulating volume is decreased splanchnic vasoconstriction occurs early and profoundly,⁸ even before the onset of systemic hemodynamic instability.⁹ Splanchnic vasoconstriction is also induced by vasoactive medications, nicotine, and cocaine abuse. GI ischemia occurs only when blood flow is decreased to below 50% of the basal rate.^{10,11}

During splanchnic hypoperfusion, blood flow within the bowel wall is unevenly distributed among its different layers. The mucosa is relatively protected compared with the serosal layer.¹² However, superficial mucosal layers are susceptible to ischemia because of the high metabolic demand¹ and countercurrent diffusion of oxygen. Blood flow is unevenly distributed within the mucosal layer, with patchy distribution in ischemic and nonischemic areas because of microcirculatory shunting.¹³⁻¹⁵ This patchy distribution may be the reason for normal mucosal blood flow measurements despite the presence of mucosal ischemia. Therefore ischemia cannot be detected only based on blood flow measurements. This ischemia associated with a normal vessel anatomy is called *NOMI*.

Ischemic Damage

Mild ischemia does not induce any histologic damage.¹⁶ After the complete cessation of splanchnic blood flow, extensive damage occurs within 30 minutes after the disappearance of villi and exposure of subepithelial spaces. Upon reperfusion, the remaining epithelial layers retract and are shed into the lumen.¹⁷ Three phases are typically distinguished and often occur simultaneously and remittently.

Ischemic Phase

The immediate effect of decreased oxygen utilization is ATP depletion. This leads to rapid derangement of tight junctions between enterocytes and malfunctioning of membrane-bound pumps. Increased mucosal permeability and damage decrease intestinal epithelial barrier function and bacterial translocation, thus allowing bacteria to enter the circulation.¹⁸ Another effect of cellular hypoxia is the conversion of xanthine dehydrogenase into xanthine oxidase (XO), which is harmless at this stage. Subsequent tissue necrosis triggers an inflammatory response, resulting in cytokine release. Most effects of the ischemic phase are localized and remain clinically undetected for many hours. These

conditions may persist until the initiation of a systemic inflammatory response or transmural gangrene by reperfusion.

Local Effects of Reperfusion

Once the blood flow is restored, oxygen enters the ischemic tissue after the dissolution of emboli or after the improvement of general circulation. At this stage, XO converts oxygen into various reactive oxygen species (ROS) that induce protein and DNA damage.¹⁹ The damage to mucosa, blood vessels, and submucosal tissues is not only intensified but also spreads to adjacent regions by the diffusion of the small ROS molecules. Physiologically present ROS scavengers like glutathione, catalase, and superoxide dismutase limit these ROS-induced effects; however, their efficacy is limited because they soon undergo depletion.

Systemic Effects of Reperfusion

Reperfusion releases toxic products, XO, proinflammatory cytokines, and activated neutrophils into systemic circulation.²⁰ In animal studies, liver and lung damage has been attributed to activated neutrophils released from a reperfused ischemic bowel induce liver and lung damage.¹⁹ Thus, reperfusion leads to the amplification and diffusion of ischemic damage.

■ DIAGNOSTIC METHODS

Introduction

For a diagnosis of GI ischemia three parameters should be considered: the clinical presentation (complaints), vessel anatomy, and proof of ischemia.

Clinical Presentation

Most patients with nonocclusive ischemia are critically ill, and their medical history is of limited value. Typical complaints of patients with occlusive mesenteric ischemia include postprandial pain, weight loss, fear of eating, adjusted meals, and unexplained diarrhea.²¹⁻²³

Duplex Ultrasonography

Duplex ultrasonography of the splanchnic arteries provides accurate results in 80% to 90% of cases when performed by experienced professionals. Measurement of flow velocity at the origin of the CA and SMA by considering the respiratory cycle allows the assessment of stenoses.^{24,25} However, duplex ultrasonography is unsuitable for most critically ill patients because it is very operator dependent; moreover, vessels cannot be visualized in 10% to 15% of patients because of the presence of GI gas.

Computed Tomography Angiography

Computed tomography (CT) angiography (CTA) during the arterial and venous phases after the intravenous injection of a contrast by using a slice thickness of 1 mm, followed by 3D reconstruction of the vessel, is increasingly being performed in patients admitted to ICUs. CTA is accurate for detecting acute mesenteric ischemia.²⁶ A meta-analysis showed that CTA is the most reliable diagnostic tool.²⁷ Advantages of CTA include minimal invasiveness, short scan time, high-resolution vessel visualization and provision of additional information on bowel pathology or perfusion. It has recently been reported as accurate diagnostic test for NOMI as well, characterized by a reduced SMA diameter. It was suggested that incorporation of CTA in the workup for suspected NOMI might improve the mortality.²⁸

Magnetic Resonance Angiography

MRA has largely replaced CT angiography, despite its potential for 360° view of the vessels, quantitative blood flow measurement, and

oxygen content. The faster scan times and higher spatial resolution resulted in superior results for CTA in comparative studies, using angiography as the gold standard.²⁹

Digital Subtraction Angiography

Digital subtraction angiography (DSA) of splanchnic vessels, which was previously used as the diagnostic gold standard, is now used only in endovascular procedures and is usually preceded by diagnostic CTA. When a state-of-the-art CT scan is not available, multiplane aortal and selective angiography is performed for accurate diagnosis.

Endoscopy and Surgery: Inspection of the Mucosa and Serosa

Endoscopy allows the examination of mucosal layers. In contrast, abdominal inspection during surgery only allows the examination of the serosal side of the bowel. Because the mucosa is affected by ischemic changes at an early stage, when the serosa is still completely normal, endoscopy will show ischemia at stages where laparotomy yields normal findings.³⁰ The following three points should be considered: (1) Endoscopy is more sensitive for diagnosing early ischemia and often does not detect transient or mild ischemia; therefore one cannot exclude ischemia despite obtaining normal findings during endoscopic examination.¹⁶ (2) Endoscopy cannot distinguish between mucosal and transmural ischemia, even when endoscopy shows deep ulcerations or gangrenous-appearing mucosa and the serosa can be spared. (3) Transmural ischemia can only be detected surgically. Therefore laparoscopy or laparotomy is indicated when transmural ischemia is suspected and when bowel resection is indicated. On the other hand, endoscopy is performed to rule out moderate to severe ischemia.

Laboratory Tests

Serologic tests are of limited use for detecting ischemia. Classical markers like leukocyte count and arterial lactate level are not sensitive and specific for detecting ischemia. Intestinal fatty acid-binding protein and D-lactate are the most promising serologic markers^{31,32}; however, clinical data on these markers are sparse.³³⁻³⁵

Measurement of PCO₂ (Tonometry)

Measurement of intraluminal PCO₂ levels can detect ischemia irrespective of blood flow or metabolism. This extra CO₂ is released during ischemia and results from buffering by local bicarbonate of large amounts of tissue (lactic) acids produced during anaerobic metabolism. Because CO₂ diffuses readily from the mucosa to the lumen, intraluminal PCO₂ levels reflect mucosal CO₂ levels. The relation between CO₂ and ischemia was first described in the heart and skeletal muscles and in the stomach.^{36,37,38} Measurement of intraluminal PCO₂ levels was first published by Boda in 1959.³⁹ This technique was subsequently popularized by Fiddian-Green and was thereafter marketed as tonometry (Fig. 162-1A). Alternative PCO₂ measurement techniques have been recently validated by Boda almost 50 years after his first publication.⁴⁰⁻⁴¹ Tonometry is an important technique for detecting splanchnic ischemia in critical care patients. Moreover, tonometry allows the selection of patients who can benefit from the treatment of splanchnic stenoses.⁴²⁻⁴⁴ Measurement of PCO₂ levels is the only valid test for detecting GI ischemia. Increased intraluminal to arterial PCO₂ gradient is an indicator of ischemia. Normal gastric-arterial PCO₂ gradient in the stomach is below 0.9 kPa (7 mm Hg),⁴⁵ and that in the jejunum is 1.4 kPa.⁴⁶ The relation between PCO₂ gradient and blood flow is characterized by an unchanged gradient, with an increase starting when the splanchnic blood flow falls below 30% to 40% of baseline values (Fig. 162-2).^{30,45}

FIGURE 162-1 ■ Techniques for measuring intraluminal PCO_2 levels. **(A)** Tonometry.¹¹ PCO_2 levels can be measured using a specialized balloon-tipped catheter placed in the stomach and the small or large bowel. Because CO_2 diffuses rapidly through different membranes, mucosal PCO_2 (PmPCO_2) levels will be equal to gastric lumen PCO_2 levels. Because CO_2 permeates into the balloon, balloon PCO_2 levels reflect PmPCO_2 levels. Balloon PCO_2 levels are measured from the air that is aspirated and inflated automatically into the balloon by using a modified capnograph called Tonocap (Datex-Engström). **(B)** Balloonless intraluminal PCO_2 measurement.⁴³ In this, PCO_2 levels are measured using a balloonless catheter in which air flows through a tube that is CO_2 permeable only at the intragastric tip and that is connected to the capnograph on the sampling side.

Clinical Application of PCO_2 Tonometry

Because splanchnic ischemia is one of the earliest events during circulatory stress and typically begins when all other systemic parameters are within a normal range, it is called “the canary of the body.”⁴⁷ Like a canary, which was once used in coal mines to detect toxic levels of

FIGURE 162-2 ■ Blood flow, ischemia, and luminal PCO_2 levels.¹¹ Reduction in splanchnic blood flow to approximately 50% does not increase luminal PCO_2 levels and does not induce tissue damage. Further reduction below approximately 30% of the basal blood flow results in a gradual increase in luminal PCO_2 levels and characteristic ischemic tissue damage. Blood flow is indicated by the blue line, and intraluminal PCO_2 is indicated by the red line. The dotted lines indicate anaerobic threshold of the tissue.

mine gas, measurement of PCO_2 levels may be a good, inexpensive, and relatively early indicator of an impending problem.⁴⁸

Although measurement of PCO_2 levels is a promising method for detecting ischemia, it is rarely used. This is mainly because first-generation tonometers involving saline and blood gas analyzers are difficult to use, time-consuming, and error prone. In addition, there is uncertainty regarding the effects of and need for acid suppression and food ingestion. These issues have now been resolved by using air-based PCO_2 measurement devices (Tonocap device), by inducing potent acid suppression, and by ensuring standardized meal consumption during testing.

Different tonometry data were obtained from non-ICU patients with occlusive ischemia. Tonometry during a 10-minute exercise test measured PCO_2 during submaximal exercise allowed to detect ischemia in the stomach and small bowel with a 78% sensitivity and 92% specificity.⁴² This test has been successfully used to select patients with single-vessel stenosis for treatment and follow-up.⁴ Using strict testing conditions, including acid suppression and standard meal consumption, provided similar accuracy with more physiologic 24-hour tonometry.⁴⁹⁻⁵⁰ This was based on an initial observation in a study performed in 1991,⁵¹ followed by studies with conflicting results.⁵²⁻⁵⁴ An imminent bowel infarction is characterized by an increased PCO_2 level (often above 15 kPa) for several hours. We detected an entire spectrum of splanchnic ischemic disorders ranging from asymptomatic stenoses to single- and multivessel stenoses and imminent bowel infarction by using this test.⁵⁵

CLINICAL PRESENTATIONS OF SPLANCHNIC ISCHEMIA

Introduction

Splanchnic vascular disorders encompass various acute and chronic (non)occlusive and aneurysmal disorders that affect the vessels in the abdominal viscera. Ischemic disorders are classified based on vessel anatomy and ischemia (Fig. 162-3). Acute splanchnic ischemia is caused by arterial embolism, arterial and venous thrombosis, arterial stenosis, or NOMI. For an intensivist, NOMI is the most common problem and hence will be discussed first. Discussion on occlusive ischemia will focus on different and often underappreciated clinical presentations, diagnostic problems, and treatment issues, with a special emphasis on ICU care.

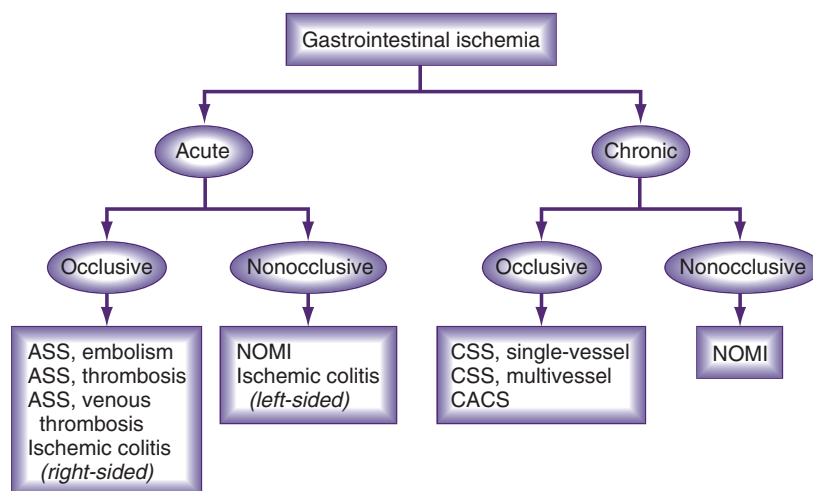

FIGURE 162-3 ■ Classification of gastrointestinal vascular diseases and ischemia.⁵³

Nonocclusive Mesenteric Ischemia

Critically Ill Patients and Major Operations

In gastroenterology and surgery, NOMI is probably a rare disorder that can cause ischemic colitis⁵⁶ or acute splanchnic infarction.⁵⁷ It can also lead to chronic complaints related to vascular spasm that are comparable to those associated with chronic splanchnic ischemia. Treatment with vasodilators is successful in the majority of patients and referred to as *abdominal migraine*.⁵⁸

NOMI is caused by physiologic responses to decreased intravascular blood volume. Early and profound splanchnic vasoconstriction that accompanies major operations may lead to splanchnic ischemia and eventually adverse prognosis.^{59,60} Similarly, in patients with acute pancreatitis, gastric mucosal ischemia is associated with a worse outcome.⁶¹ The relevance of this finding was reinforced by a recent randomized study that examined the effects of probiotics on acute pancreatitis. This study, which investigated the potential beneficial effects of probiotics supplemented with early feeding on acute pancreatitis, showed that mortality was significantly higher in patients receiving probiotics and was associated with bowel infarction.⁶²

NOMI may play a key role in the pathogenesis of multiple organ dysfunction syndrome (MODS). Although endotoxemia directly causes mucosal microcirculatory disturbances⁶³ and increases gut-derived cytokine and endotoxin levels in patients with MODS,^{64,65} there is no definite proof that NOMI is associated with the pathogenesis of MODS.

Hemodialysis Patients

NOMI is common in hemodialysis patients⁶⁶ and may lead to bowel infarction, with a 45% mortality rate.⁶⁷ This complication has been reported in 0.5% to 0.9% of hemodialysis patients.⁶⁷⁻⁶⁹ The main risk factor for NOMI is hypotension. Therefore close monitoring and prevention of hypotension during hemodialysis are crucial to prevent NOMI.⁶⁷

Medications

Many drugs, including digoxin and NSAIDs, may induce or aggravate NOMI. NSAIDs affect the integrity of the GI mucus and bicarbonate layer and decrease mucosal perfusion. Alpha-adrenergic agents like epinephrine and dopamine decrease GI perfusion, and beta-adrenergic agents like dobutamine and dopexamine maintain mucosal perfusion.⁷⁰⁻⁷² The clinical importance of these differences is probably very small because recent comparative studies have failed to show differences in mortality between patients using norepinephrine plus

dobutamine and those using epinephrine⁷³ or norepinephrine versus dopamine.⁷⁴

Occlusive Mesenteric Ischemia

The incidence of asymptomatic splanchnic stenoses (also called *chronic splanchnic disease*) ranges between 8% and 70% in populations with other manifestations of atherosclerotic diseases. Three causes of vascular obstruction can be distinguished in chronic mesenteric ischemia: atherosclerosis, external compression by the diaphragm (celiac artery compression syndrome), and vasculitis. The largest group consists of patients with atherosclerosis. Coronary artery disease, cerebrovascular disease, peripheral arterial disease, and atherosclerotic disease of splanchnic vessels have many overlapping symptoms. The incidence of symptomatic occlusive splanchnic ischemia or chronic splanchnic syndrome is relatively low, with 4 to 5 cases per 100,000 persons yearly.⁷⁵ The incidence of acute splanchnic ischemia is low but increases sharply with age. A recent autopsy study showed that 1.2% of all deaths in patients over 80 years were caused by acute splanchnic ischemia.⁷⁶ The diagnosis was suspected in the minority of patients.⁷⁷

Risk factors of splanchnic atherosclerosis are comparable to those of other atherosclerotic diseases.⁷⁸ However, patients with splanchnic stenoses are less overweight, less diabetic, and less dyslipidemic and are often women.²³ Serial duplex ultrasonography showed progression of atherosclerotic stenoses in the visceral artery in approximately 20% of patients. This progression of lesions may be especially important in multivessel chronic splanchnic disease that carries a considerable risk for acute splanchnic infarction.⁷⁹

External compression by the arcuate ligament of the diaphragm is the predominant cause of single-vessel CA stenosis in young adults. Because they are otherwise healthy, these patients rarely will be seen at the intensive care.^{44,80}

Splanchnic vasculitis is a rare cause of ischemia and is usually an unexpected finding in patients operated for bowel perforation or bleeding. The main causes include periarteritis nodosa, systemic lupus erythematosus, and rheumatoid arthritis.

Multivessel Involvement

Most patients with significant stenoses in two or three of the main splanchnic vessels experience ischemic complaints.⁷⁵ Often, the typical presentation is no longer postprandial pain, altered eating habits, or weight loss. Although most patients experience typical complaints for many years, these complaints become less typical over time because the patients grow accustomed to the pain, and it becomes part of their

lives. Moreover, in the end stage of the disease, the pattern of complaints can become extremely atypical, with abdominal fullness or loss of appetite being the main complaint. Consequently, these patients may become severely cachectic and have a high risk of bowel infarction. A study reported bowel infarction in 30% and 60% patients with severe multivessel involvement after 1 and 4 years, respectively.⁷⁹ Prognosis is poor after the development of acute ischemia, and mortality rate increases to 80% after the development of bowel infarction.^{57,81} Therefore patients with unexplained pain, malaise, and/or weight loss who develop multivessel stenosis should be suspected of having end-stage ischemia.

Acute Mesenteric Ischemia

Acute splanchnic ischemia is defined as the sudden cessation of splanchnic mucosal perfusion. It should be suspected in patients with acute severe abdominal pain without any obvious diagnosis. Classically, the severity of pain is out of proportion to the (almost normal) physical findings. In elderly patients, acute splanchnic ischemia is accompanied with unexplained confusion. If left untreated, acute splanchnic ischemia results in bowel necrosis within 8 hours. This necrosis may remain clinically silent for several hours or days as long as the necrotic segment remains nonperfused and isolated from circulation.³⁰ Subsequently, MODS develops rapidly, followed by death, after reperfusion or perforation of the gangrenous bowel. Prognosis also depends on the cause of the infarction and ranges from approximately 32% in patients with venous thrombosis and 54% in patients with arterial embolism to 70% to 80% in patients with acute arterial thrombosis and nonocclusive ischemia. Overall survival after acute splanchnic ischemia has improved over the past four decades.⁸¹

Unexpected Splanchnic Ischemia in ICU Patients

As mentioned above, many patients with splanchnic stenoses either remain undiagnosed or experience no complaints. However, increased metabolic demand during major abdominal surgery or in inflammatory disorders like pancreatitis or cholecystitis may easily cause ischemia in patients with vascular stenoses. This is also observed in critically ill patients who are fed enterally and in patients in whom the burden of enteral feeding cannot be matched with adequate perfusion.⁸² Therefore ischemia should be considered in patients with a prolonged and complicated course of cholecystitis or pancreatitis. In these patients, CTA may detect a multivessel disease, and endovascular treatment may dramatically improve the clinical course within days.

Ischemic Colitis

Left-sided ischemic colitis is a well-defined, nonocclusive disorder in most patients and is associated with normal findings on an angiogram.^{56,57} Most cases of spontaneous ischemic colitis are not preceded by shock states and are diagnosed because of unexpected findings during endoscopy for unexplained abdominal cramps, diarrhea, or blood loss. Most patients with spontaneous left-sided ischemic colitis recover within days or weeks and rarely come to the attention of the intensivist.

Ischemic colitis after aortic surgery frequently develops in ICU patients (20%-27%) who undergo an open repair of a ruptured abdominal aneurysm and is associated with an average mortality rate of 48%.⁸³⁻⁸⁶ Sigmoid ischemia after elective aortic surgery has been reported in less than 2% of patients.⁸⁷ Risk factors of sigmoid ischemia include preoperative shock, significant blood loss, and persistent hemodynamic instability. The role of IMA ligation in the development of sigmoid ischemia is debatable.⁸⁴ Increased use of endovascular stent placement for both acute and elective treatment of abdominal aortic aneurysms has sharply decreased mortality rate, duration of ICU stay, and incidence of ischemic colitis after abdominal aortic aneurysm repair.⁸⁸ However, sigmoidoscopy should be performed when patients remain unstable for over 48 hours after aortic repair.

Left-sided ischemic colitis (discussed above) should be differentiated from right-sided ischemic colitis.^{89,90} The latter is associated with

significant impairment of SMA inflow, which in turn is associated with adverse prognosis, increased surgery rates, and increased mortality.⁹⁰ Right-sided ischemic colitis should be treated immediately to improve prognosis. We recommend urgent CTA to establish or rule out vessel stenoses, to rule out other pathologies, and to prevent a "blind" laparotomy.

TREATMENT

Nonocclusive Mesenteric Ischemia

Detection and Restoration of Regional Blood Flow

Rapid optimization of intravascular volume can be achieved by measuring gastric PCO₂ levels as the end point for fluid resuscitation.⁹¹⁻⁹³ However, results of small resuscitation trials involving tonometry have provided conflicting results.⁹⁴⁻⁹⁶ A recent meta-analysis involving 816 patients indicated that tonometry-guided treatment decreased mortality by 26%.⁹⁷ However, the different types of patients included in these studies (patients undergoing surgery, patients with trauma, and patients admitted to ICUs) and the small number of patients included per study may have limited the clinical significance of this conclusion.⁹⁸ An alternative might be to perform CTA to detect mesenteric vasoconstriction; however, data on experience with CTA are sparse.^{99,100}

Prevention of Reperfusion Damage

Treatment of reperfusion damage is a promising but clinically unproven approach. Some studies involving patients with early sepsis have shown that *N*-acetylcysteine is the best ROS scavenger that increases intracellular glutathione levels and NO release¹⁰¹ and improves hemodynamics¹⁰² and splanchnic ischemia.¹⁰³

Medication

Although avoidance of treatment with the splanchnic vasoconstrictors epinephrine and dopamine in patients with NOMI is appealing,^{104,105} recent studies have failed to show a difference between different catecholamines for resuscitation after fluid correction.^{73,74} Treatment with angiotensin-converting enzyme inhibitors to reduce angiotensin II levels was effective in animal studies¹⁰⁶ and only in one out of two clinical studies.^{107,108}

Feeding

Early institution of enteral nutrition may improve perfusion in addition to exerting salutary immunologic and nutritional effects. Mechanisms underlying mucosal vasodilatation due to enteric nutrition include autoregulatory responses driven by metabolic demands associated with food absorption in the lumen.¹⁰⁹ However, in extremely low or no-flow states, enteral nutrition can be very harmful and may induce infarction and therefore should be administered cautiously.^{82,110} This may explain the high rate of bowel infarction in the previously mentioned study on probiotic pancreatitis where rapid high-volume feeding was used as a standard procedure.⁶²

Chronic Occlusive Mesenteric Ischemia

Workup: Preoperative Feeding?

Patients with occlusive splanchnic ischemia and severe weight loss should not be fed preoperatively, enterally, or parenterally. Theoretically, increased body weight could improve immune status and postoperative recovery in patients with occlusive splanchnic ischemia. However, in patients with critically narrowed vessels, bowel blood flow cannot be increased to process nutrients. This may lead to increased ischemia or bowel infarction. Parenteral feeding should also be avoided in patients with severe CA and SMA stenoses. Double vascularization of the liver is compromised because both the portal vein and hepatic artery arise from these vessels. Parenteral feeding may lead to hepatic ischemia or bowel infarction because of intramesenteric shunting.⁵⁵ Patients with multivessel critical stenoses should be treated by

performing urgent revascularization, and feeding should be avoided until the blood flow is restored.

Treatment

Treatment of chronic mesenteric ischemia is based on the restoration of vascularization and is outside the scope of this chapter.

Acute and Acute-on-Chronic Mesenteric Ischemia

Patients with severe and/or progressive complaints and with multivessel stenoses should be treated urgently (Table 162-1). Immediate treatment should be indicated when signs of bowel infarction, including peritoneal symptoms, progressive leukocytosis, and elevated lactate or C-reactive protein level, are observed. These biomarkers have limited diagnostic value. However, in patients with established multivessel stenoses, an increase in the levels of these biomarkers is a potent indicator of ischemic damage. The treatment can be divided in six chronological steps.

TABLE 162-1 Summary of Treatment Options for Acute Splanchnic Ischemia

NONOCCLUSIVE MESENTERIC ISCHEMIA (NOMI)

- Exclude vascular occlusions by performing computed tomography angiography (CTA)
- Perform aggressive volume resuscitation, with normalized PCO_2 level as the end point
- Avoid alpha-adrenergic drugs when possible
- Administer intraarterial [superior mesenteric artery (SMA)] papaverine or prostaglandin E_1 in severe cases

ACUTE AND ACUTE-ON-CHRONIC SPLANCHNIC ISCHEMIA

- Administer intravenous fluids to restore intravascular volume
- Induce acid suppression (proton pump inhibitors)
- Avoid oral food intake
- Perform urgent CTA for diagnosis and revascularization planning
- Use heparins
- Induce revascularization within hours or days

Acute and Acute-on-Chronic Splanchnic Ischemia with Possible Bowel Infarction

- Assess bowel viability (after revascularization) and resect necrotic bowel; consider a second look

Postoperative Treatment

- Maintain optimal fluid status, and avoid alpha-adrenergic drugs when possible
- If abdominal complaints recur, perform CTA to rule out vascular occlusion; if vessels are patent, suspect reperfusion syndrome
- Initiate treatment with warfarin or thrombocyte aggregation inhibitors after the recovery of bowel mucosa

Treatment of Reperfusion Syndrome

- Stop oral food intake
- Initiate total parenteral nutrition for 2-5 weeks

ISCHEMIC COLITIS

Right-Sided (Ascending Colon) Ischemic Colitis

- Perform urgent CTA
 - a. In the presence of superior mesenteric artery (SMA) occlusion or stenosis, initiate a treatment similar to that for acute splanchnic syndrome
 - b. In the presence of a normal vasculature, initiate a treatment similar to that for left-sided ischemic colitis

Left-Sided Ischemic Colitis

- Initiate aggressive volume replacement, and avoid alpha-adrenergic drugs
- Consider performing bowel decompression
- Consider laparotomy and partial colectomy in the presence of
 - a. persistent sepsis, fever, and hemodynamic instability
 - b. proven ischemic colitis (by endoscopy) despite administering treatment for NOMI
 - c. diarrhea and protein loss for >14 days after surgery

1. Fluid Resuscitation and Metabolic Demand Reduction

Restoration of intravascular volume should be the first treatment because most patients show poor food and fluid intake before admission. Usually, 2000 to 4000 mL of crystalloid is infused every 24 hours depending on the age and clinical condition of patients. Reduction of metabolic demand can be achieved by avoiding enteral and parenteral feeding and by administering proton pump inhibitors that suppress acid secretion.

2. Assessment of Vessel Anatomy and Ischemic Damage

Urgent CTA should be performed in patients with suspected bowel infarction. CTA provides information on vessel anatomy, calcifications, and end organ damage such as portal gas, mucosal ischemia, bowel wall edema, or pneumatosis.²⁶ Results of CTA are essential for determining treatment options and strategies.

3. Revascularization

Angiography serves as technique for stenting of the CA or SMA or to remove SMA emboli. In patients with NOMI, papaverine (30-60 mg/h for a maximum of 4 hours) or prostaglandin E_1 (bolus 0.020 mg, 0.060 mg/h for up to 72 hours) should be administered by performing selective SMA catheterization to decrease arterial spasms.¹¹¹

Endovascular treatment is the preferred next step in patients with occlusive ischemia preferably before laparotomy.^{112,113} Various options are available for treating these patients partly because of the lack of solid clinical evidence for preferring one treatment over the other.¹¹⁴ The order of preferred options for treating patients with acute ischemia is as follows: (1) antegrade endovascular treatment, (2) retrograde operative mesenteric stenting (ROMS), (3) operative retrograde revascularization, and (4) operative antegrade revascularization.

Antegrade endovascular treatment by performing percutaneous transluminal angioplasty (PTA) with stent placement can be performed through the femoral artery in the groin or through the brachial artery. Presence of occlusions in the splanchnic vessels is not a contraindication for performing antegrade endovascular treatment as the first-line strategy.¹¹⁵ In our institution, 5-year secondary patency for both the CA and SMA is 95% (Fig. 162-4).¹¹⁶

ROMS is performed in patients who cannot undergo antegrade endovascular treatment. It involves performing a small laparotomy to identify and cannulate the outflow of the SMA. A catheter is then advanced into the aorta under manual and fluoroscopic control, and PTA and stenting of the occluded SMA tract are then performed.¹¹²

Operative retrograde revascularization can be performed with long bypasses from the iliac arteries or the distal aorta to either the common hepatic artery or the SMA outflow. The main disadvantage of this procedure is that the long meandering bypasses are associated with higher risk of kinking and thrombosis or stenoses, thus increasing the likelihood of occlusion. However, the operative burden associated with operative retrograde revascularization is lower than that associated with operative antegrade revascularization.

Operative antegrade multivessel autologous revascularization provides excellent long-term results with respect to patency and clinical response.^{21,117} The downside is that the operative burden is very high because of aortic clamping. Therefore it is only suitable for relatively young patients with a good clinical condition and life expectancy.

4. Assessment of Bowel Viability and Resection

Bowel viability should be assessed only after restoring blood flow. Only irreversibly damaged bowel should be resected. A routine "second look" procedure, which is performed 24 hours after the original operation, should be performed. This approach spares most of the bowel length, thus providing the patient with a better quality of life. Patients should be administered parenteral nutrition immediately after the procedure. Complete but adjusted¹¹⁸ enteral nutrition can be restored in patients with small bowel length of greater than 50 cm and with an

FIGURE 162-4 ■ Retrograde open mesenteric stent placement: the hybrid procedure. A superior mesenteric artery (SMA) and CA celiac artery (CA) occlusion was detected in a patient with imminent splanchnic infarction. Therefore standard endovascular stenting could not be performed. **(A)** After performing a small supraumbilical laparotomy, the outflow of the SMA was controlled. Retrogradely, a 5 French sheath was introduced into the SMA, and endovascular connection between the SMA outflow and the aorta was established under manual and fluoroscopic visualization. **(B)** Subsequently, PTA and stenting of the occluded trajectory of the SMA was performed. (From Blauw et al.¹¹²) PTA, percutaneous transluminal angioplasty; SMA, superior mesenteric artery

intact ileocecal valve or in patients with small bowel length between 50 and 100 cm and without ileocecal valve.¹¹⁹ The quality of life of these patients is relatively good and is comparable to that of hemodialysis patients.¹²⁰ Therefore revascularization and resection should be considered in patients who have relatively good health but with almost completely necrotic bowel and without the clear involvement of the stomach, duodenum, liver, and pancreas.

5. Treatment of Reperfusion Damage

Risk factors of reperfusion damage after revascularization include severe and long-standing multivessel disease, end-organ damage (mucosal ulceration), and continuous abdominal pain not associated with feeding. The typical course of events in reperfusion damage during splanchnic ischemia includes initial uneventful recovery, followed by sudden deterioration 2 to 5 days after the intervention. Recurrence of abdominal pain is the most common clinical presentation; however, gastric ulceration, massive ascites, and sometimes severe hypoalbuminemia and leukocytosis may also occur.

The first action should be to exclude stent or bypass occlusion by performing CTA or duplex ultrasonography. Four measures can be considered to limit reperfusion damage: (1) stop oral food intake, (2) initiate total parenteral nutrition, (3) induce acid suppression, and (4) provide sufficient intravenous fluids. Most patients recover within 2 to 6 weeks without any lasting complications.

6. Prevention of Reocclusion and Rethrombosis

Aggressive anticoagulation treatment is essential in all patients with bypasses of stents in critical areas. Heparin treatment is recommended until the patient becomes completely anabolic. Subsequently, heparin can be switched to acetylsalicylic acid (100 mg) and clopidogrel (75 mg) once daily or to warfarin if they are indicated for other reasons. Starting warfarin early may be hazardous as its absorption may be unpredictable, resulting in severe anticoagulation and severe GI bleeding events.

Ischemic Colitis

In most cases, left-sided ischemic colitis resolves spontaneously with only fluid resuscitation. Endoscopic bowel decompression should be considered if the colon is markedly dilated. Surgery is restricted to patients with transmural irreversible ischemia. Sigmoidoscopy should be considered after aortic surgery in patients with persistent hemodynamic instability lasting for over 48 hours. Right-sided ischemic colitis is an indicator of main vessel inflow stenosis.¹²¹ CTA should be considered in patients with right-sided ischemic colitis.

KEY POINTS

1. Nonocclusive mucosal or mesenteric ischemia (NOMI) is the result of blood flow redistribution following adaptation of the blood flow distribution in all types of circulatory stresses. It is a common disorder in patients admitted to intensive care units.
2. The first-line treatment of NOMI involves aggressive volume resuscitation and avoidance of alpha-adrenergic drugs. In severe cases of imminent bowel infarction, the second-line treatment should include intraarterial papaverine or intravenous prostaglandin E1.
3. In patients with severe NOMI and with imminent bowel infarction, computed tomography angiography (CTA) with 1-mm slices should be performed to exclude vascular stenoses and alternative pathology.
4. Splanchnic vessel stenoses are common but remain asymptomatic in most patients. In critically ill patients, endovascular reconstruction can be achieved in most cases even if asymptomatic stenoses may be the root cause of unimproved abdominal complaints.
5. Retrograde mesenteric stenting should be considered in patients who cannot undergo antegrade stenting before surgical revascularization.
6. Enteral and parenteral nutrition increases splanchnic perfusion and can exert detrimental effects. In addition, enteral and parenteral nutrition induces infarction in patients with highly decreased splanchnic blood flow because of splanchnic stenosis or severe shock syndrome. In these patients, nutrition should be withheld or should be initiated with utmost caution until the improvement of splanchnic perfusion through revascularization or improved hemodynamics.
7. Colonoscopy is the gold standard for diagnosing early mucosal ischemic colitis, and laparotomy is the gold standard for diagnosing transmural or gangrenous ischemic colitis.
8. Right-sided ischemic colitis is an indicator of significant large vessel inflow stenosis.

DEFINITIONS

To date, the most common method to measure intraabdominal pressure (IAP) is the intravesical technique via a urinary catheter (often referred to as *urinary bladder pressure*).¹⁻³ The mean value of IAP in hospitalized patients is 6.5 mm Hg (range, 0.2-16.2 mm Hg).⁴ In critically ill patients, IAP is typically higher (12-16 mm Hg).⁵

Intraabdominal hypertension (IAH) is graded from I to IV based on IAP (grade I: 12-15 mm Hg; grade II: 16-20 mm Hg; grade III: 21-25 mm Hg; and grade IV: above 25 mm Hg).

Abdominal compartment syndrome (ACS) is defined as the presence of sustained IAP of greater than 20 mm Hg associated with attributable organ dysfunction.

Primary ACS is a condition associated with injuries or diseases in the abdominopelvic region.

Secondary ACS refers to a condition that does not originate from injuries or diseases in the abdominopelvic region.

DAMAGE CONTROL

Patients undergoing surgery for major bleeding are at risk for entering the "bloody vicious circle" of acidosis, hypothermia, and coagulopathy and, as a result, exsanguination. Prevention of this scenario is the rationale of damage control.^{6,7} Damage control has two goals: (1) quick control of bleeding and (2) prevention of further contamination from hollow viscous perforations. In this, the abdomen is temporarily closed without fascial approximation, and the patient is triaged to the intensive care unit (ICU) for resuscitation and correction of abnormal bloody vicious circle physiology. However, damage control has resulted in new challenges, including diagnosis and management of ACS and management of open abdomen and early multiple organ failure (MOF).

Abdominal Decompression

Traditionally, abdominal decompression has been achieved through a full midline laparotomy. Recently, other techniques such as transverse laparotomy, percutaneous drainage, and minimally invasive linea alba fasciotomy have been described as potentially useful methods in selected cases. Decompressive laparotomy can be performed in ICUs in extreme cases. However, it is generally preferred to be performed in operating rooms, especially when further intraabdominal procedures are anticipated.

HISTORICAL PERSPECTIVE

Studies on IAH have been performed for over 150 years.^{8,9,10} Results of these studies had little impact until pediatric surgeons in the 1950s recognized the fatal consequences of acutely closing large congenital abdominal defects. Silo closure with gradual reduction of abdominal defect was recommended to prevent fulminant organ failure.¹¹ In the 1980s, vascular surgeons described ACS after abdominal aortic aneurysm surgery and popularized the use high IAP as a criterion for re-exploration.¹ However, it was not until the 1990s, when trauma surgeons adopted the liberal use of the damage-control strategy, that sufficient number of patients survived to allow the characterization of this elusive complication.¹²⁻¹⁵ In addition, it was recognized in the

1990s that ACS occurred in a variety of scenarios such as extreme constipation,¹⁶ ovarian hyperstimulation,¹⁷ noninvasive ventilation,¹⁸ pancreatitis,¹⁹ and severe burns.²⁰

INTRAABDOMINAL PRESSURE MEASUREMENT

Clinical examination of the abdomen for monitoring IAP can provide inaccurate results.^{21,22} The intravesical technique involving the use of a standard urinary catheter is the most reliable and least invasive method for monitoring IAP.²³ The intravesical technique has been shown to correlate well with IAP measured directly using a laparoscopic insufflator.²⁴ The vesical route is more accurate for monitoring IAP than rectal and gastric routes.²⁴ Animal studies have shown that the pressure in the inferior vena cava correlates well with the vesical pressure but is more invasive.^{25,26} Several proprietary devices are available to intermittently monitor urinary bladder pressure. Unfortunately, IAP measurements are rarely obtained more often than every 4 hours because of logistic problems. These shortcomings have been overcome by developing and validating a continuous IAP measurement technique.²⁷

PATHOPHYSIOLOGY

The volume of the abdominal cavity is limited by its least tensile component, the fascia. Increased pressure can be due to an increase in the volume of abdominal contents or because of a decrease in the volume of the "container" (Table 163-1). After IAP increases to greater than 20 mm Hg, the abdominal cavity is on the steep portion of its pressure-volume curve, and as a result, small increases in content volume or decreases in cavity volume can cause dramatic increases in IAP. This is when close monitoring of IAP (preferably continuously) and organ dysfunction is essential for timely intervention.

PATHOPHYSIOLOGIC RESPONSE OF SPECIFIC ORGANS

Cerebral Perfusion

Increased IAP forces the diaphragm cephalad, thus increasing the intrathoracic pressure, which impedes venous return from the brain. This increases intracranial pressure (ICP) and consequently decreases the cerebral blood flow.²⁸⁻³⁰

Cardiac Function

Increased IAP impedes venous return to the heart, thus decreasing preload. Simultaneously, left ventricular afterload increases because of increased systemic vascular resistance. Increased intrathoracic pressure also increases right ventricular afterload, leading to right dilation with leftward displacement of the ventricular septum and impairment of left ventricular filling.³¹⁻³⁴ Low cardiac index (CI) is a typical finding associated with ACS. Low CI usually does not respond to fluid challenges; moreover, ongoing volume loading can lead to the "futile crystalloid cycle" (described below, see Fig. 163-1). An increase in CI in response to decompression is a predictor of outcome.⁵

Respiratory Function

Increased IAP pushes the diaphragm into the thoracic cavity, thus decreasing thoracic compliance. Therefore, increased airway pressure is required to restore the functional residual lung volume for oxygenation during mechanical ventilation.^{34,35} Airway pressure promptly decreases in response to abdominal decompression. However, this cannot be used to differentiate between survivors and nonsurvivors.⁵

| TABLE 163-1 Causes of Intraabdominal Hypertension and Abdominal Compartment Syndrome | |
|---|--|
| INCREASED ABDOMINAL CONTENTS | DECREASED ABDOMINAL VOLUME |
| Ascites | Reduction of large long-standing hernia |
| Hemoperitoneum | Direct closure of large, long-standing abdominal wall defect |
| Visceral edema | Circumferential abdominal wall burn |
| Abdominal packs | Continuous positive-pressure ventilation |
| Peritonitis | |
| Retroperitoneal edema (pancreatitis) | Retroperitoneal edema (pancreatitis) |
| Large pelvic and retroperitoneal hematoma | Large pelvic and retroperitoneal hematoma |
| Intestinal obstruction | |
| Ileus | |
| Gastric distention (esophageal ventilation) | |
| Abdominal aortic aneurysm | |
| Severe constipation | |
| Large abdominal tumor (chronic) | |
| Morbid obesity (chronic) | |
| Pregnancy (chronic) | |

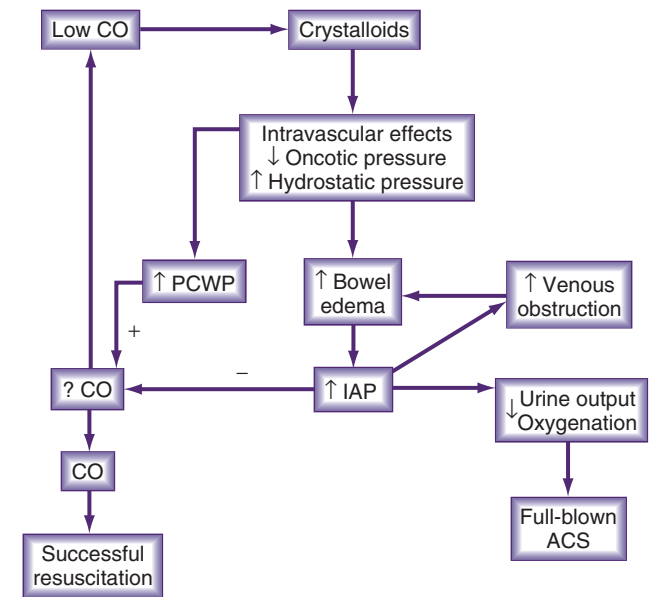

FIGURE 163-1 ■ Futile crystalloid preloading. ACS, abdominal compartment syndrome; CO, cardiac output; IAP, intraabdominal pressure; PCWP, pulmonary capillary wedge pressure; ↑, increased; ↓, decreased; +, positive effect; −, negative effect.

Monitoring of airway pressure is important during attempted primary fascial closure after laparotomy when ACS is a possible complication.

Renal Function

Oliguria or anuria is a typical sign of ACS. Mechanisms responsible for decreased renal function include direct compression of the renal parenchyma, decreased perfusion of the kidneys, and increased water and sodium retention due to the activation of renin-angiotensin system.³⁶⁻³⁸

Gut Function

Increased IAP impairs splanchnic perfusion by decreasing CI and by increasing splanchnic vascular resistance. Tissue ischemia can occur in severe cases.³⁹⁻⁴² Intestinal perfusion can be assessed objectively by performing gastric tonometry. Increased gastric regional partial pressure of carbon dioxide (PrCO₂) is an indicator of impaired abdominal visceral perfusion. Combined with IAP measurements, tonometry to identify increasing PrCO₂ is an excellent adjunct for identifying impending ACS.³ Moreover, the physiologic response to effective decompression is a prompt decrease in PrCO₂, reflecting gut reperfusion.⁵ Laboratory studies have shown that ACS induces gut ischemia and that decompression-induced reperfusion primes circulating neutrophils and releases cytokines into portal circulation. This causes acute lung injury, which is similar to that induced after hemorrhagic shock and resuscitation.^{43,44} Therefore, ACS decompression can serve as a “second hit” for MOF.⁴⁵

Extremity Perfusion

Increased IAP increases femoral venous pressure, increases peripheral vascular resistance, and decreases femoral artery blood flow by as much as 65%.⁴⁶

■ CLASSIFICATION

ACS can be classified based on its duration, presence or absence of intraperitoneal pathology, and cause of increased IAP (Table 163-2).

Acute Versus Chronic

The pathophysiologic responses described above are acute phenomena in critically ill patients. However, ACS can be present in certain clinical conditions with chronic IAH, such as morbid obesity, chronic constipation, and pregnancy.⁴⁷

| TABLE 163-2 Classification of Abdominal Compartments | |
|---|--|
| SYNDROME | |
| BASIS OF CLASSIFICATION | SUBCATEGORIES |
| Time frame | Acute Chronic |
| Relation to peritoneal cavity | Primary Secondary |
| Etiology | Trauma Burn Postoperative Pancreatitis Bowel obstruction Ileus Abdominal aortic aneurysm Oncologic Gynecologic |

Primary Versus Secondary

Primary ACS typically develops after a damage-control surgery with temporary abdominal closure.⁴⁸ As time progressed, intraabdominal bleeding and bowel edema (secondary to resuscitation) caused the volume of the intraabdominal contents to increase IAP, thus precipitating ACS. Primary ACS can also occur in patients who do not respond to nonoperative management of abdominal organ injuries because of bleeding.⁴⁹

Secondary ACS typically occurs in the setting of severe shock requiring massive resuscitation in the absence of intraperitoneal pathology or injury.³ Secondary ACS is more elusive, which delays its diagnosis.⁵⁰ Typical causes of secondary ACS are hypovolemic shock associated with multiple open extremity fractures, unstable pelvic fractures, penetrating chest injuries,⁵¹ and severe burns.^{52,53}

■ EPIDEMIOLOGY

Incidence

Because of variable definitions and patient populations, the reported incidence of ACS among high-risk patients with trauma who are undergoing laparotomy varies from 2% to 36%.^{15,54} A prospective study by Malbrain showed that the incidence of ACS in medical ICU patients was 2%.⁵⁵ Changes in treatment strategies also affect the incidence of ACS. For example, Meldrum et al.⁵⁶ and Balogh et al.³ studied similar traumatic shock populations, and both reported that the incidence of ACS was 14%. These two studies were performed 6 years apart. The earlier series by Meldrum only considered primary ACS; moreover, this series was performed when liberal use of the open abdomen was just initiated. The later series by Balogh reported that the abdomen was left open initially in almost all patients undergoing damage-control laparotomy and suggested that this was associated with decreased incidence of primary ACS. However, the previously unrecognized secondary ACS is now an equally prevalent clinical entity.

If IAH is used as a surrogate for ACS, the incidence is higher but similarly inconsistent. In surgical patients with different IAP cutoff points for defining IAH, the incidence varies from 33% to 81%.^{23,38} In medical patients, the incidence of IAH (IAH > 12 mm Hg) is only 18%.⁵⁵ Using a cutoff value of 20 mm Hg, Balogh and coworkers reported a 39% incidence in a cohort of patients who experienced severe traumatic shock.⁵⁷

Outcome

Full-blown ACS emerged in the mid-1990s as an epidemic in trauma centers worldwide and was closely linked to deaths associated with early fulminant MOF. With more timely diagnosis and treatment, more than 50% afflicted patients are now surviving this chronic critical illness.^{3,53}

■ PREDICTION AND DIAGNOSIS

Potential risk factors of ACS include severe hemorrhagic shock, high-volume crystalloid resuscitation, damage-control laparotomy, high injury severity score, and markedly elevated PrCO₂ level.^{42,58,59} Studies on secondary ACS have identified resuscitation fluid volume thresholds that warrant IAP monitoring. Maxwell et al. recommended that IAP should be monitored when resuscitation volume exceeds 10 L of crystalloid fluid or 10 units of packed red blood cells.⁶⁰ Ivy et al. suggested that the trigger to initiate IAP monitoring should be greater than 0.25 L/kg of crystalloid resuscitation.^{20,52} Biffl et al. reported that both these cutoffs are ineffective and recommended the following thresholds: 6 L of crystalloid fluid or ≥6 units of packed red blood cells in a 6-hour period in patients with a base deficit of greater than 10 mEq/L, especially when a vasopressor agent is required.⁵³

Multiple logistic regression analysis was performed using a prospective database of patients who experienced a major torso trauma

TABLE 163-3

Independent Predictors of Postinjury Primary and Secondary Abdominal Compartment Syndrome

| | ED MODEL | ICU MODEL |
|---------------|---|--|
| | INDEPENDENT PREDICTORS | INDEPENDENT PREDICTORS |
| Primary ACS | To OR < 75 min Crystalloids ≥ 3 L | Temp ≤ 34°C GAPCO ₂ ≥ 16 Hb ≤ 8/dL BD ≥ 12 mEq/L |
| Secondary ACS | Crystalloids ≥ 3 L No urgent surgery PRBC ≥ 3 units | GAPCO ₂ ≥ 16 Crystalloids ≥ 7.5 L UO ≤ 150 mL |

ACS, abdominal compartment syndrome; BD, arterial base deficit; CI, confidence interval; ED, emergency department; GAPCO₂, carbon dioxide gap; Hb, hemoglobin concentration; ICU, intensive care unit; OR, operating room; PRBC, packed red blood cells; Temp, temperature; UO, urine output.

and who underwent standardized shock resuscitation.⁵ An emergency department (ED) model (at 3 hours in patients discharged from the ED) and an ICU model (at 6 hours in patients admitted to the ICU) were developed. Table 163-3 lists independent risk factors of primary and secondary ACS that were determined using the ED and ICU models. A receiver operator characteristic curve of 0.88 was a predictor of ACS in the ED model and of 0.99 was a predictor of ACS in the ICU model.⁵⁶

■ TREATMENT

Nonsurgical Methods

Treatment of early organ dysfunction by traditional ICU interventions is often necessary in patients with impending ACS; however, these interventions may aggravate underlying pathophysiologies. For example, ventilator strategies for increasing mean airway pressure to improve oxygenation directly increase IAH by pushing down the diaphragm. In addition, increased intrathoracic pressure impedes venous outflow from the abdominal cavity. This promotes gut edema with ongoing crystalloid resuscitation. Seminal studies performed in the mid-1990s advocated volume loading to improve low urine output in patients with moderately high IAP. Increased IAP falsely elevates central venous pressure, resulting in the underestimation of ventricular end-diastolic volume. Thus volume loading was recommended to increase preload for improving CI and for increasing renal perfusion.⁶¹ Although this makes physiologic sense, close monitoring in a standardized resuscitation protocol identified this to be ineffective in increasing CI, and if volume loading continued, it would precipitate full-blown ACS. This is referred to as the *futile crystalloid cycle* (Fig. 163-1).^{57,62}

Theoretically, other nonsurgical interventions may exert beneficial effects; however, the efficacy of these interventions is unproven.⁶³ Use of colloids and albumin may mobilize interstitial fluids into the vascular space, and use of muscle relaxants might exert a salutary effect by decreasing the tension in the abdominal wall.^{52,64}

Percutaneous Methods

If ACS is caused by acute or chronic fluid collection, its symptoms can be relieved by initiating percutaneous drainage. Case reports have described successful drainage of abdominal fluid in burn patients with secondary ACS and drainage of blood in patients with nonoperatively managed liver injuries.⁶⁴⁻⁶⁷

Surgical Decompression

Surgical decompression by opening the midline fascia along its full length remains the primary recommended intervention. Almost all reports have described a very good physiologic response to decompression. However, this does not necessarily translate into better outcomes. The best predictors of survival are postdecompression improvement in CI and urine output.^{5,51} The decision to perform surgical decompression is a difficult one because it results in an open abdomen that is associated with numerous complications. Case series have shown that early decompression is associated with better outcomes. However, patients with ACS are critically ill, and their intrahospital transfer can exert detrimental effects. Thus, if no other intraabdominal surgical intervention is anticipated, bedside decompression can be performed in the ICU. More recently, alternatives to midline laparotomy, such as transverse laparotomy and linea alba fasciotomy, were described. These approaches were popularized in cases of severe acute pancreatitis.⁶⁷ The (subcutaneous) linea alba fasciotomy can prevent peritoneal contamination in selected pancreatitis cases where laparotomy is not required, only reduction of IAP.^{68,69}

MANAGEMENT OF THE OPEN ABDOMEN

Decompressive laparotomy results in an open abdomen, and temporary abdominal closure is performed to keep the fascia open. Several methods (towel clips, Bogota bag, synthetic mesh, vacuum-assisted closure, Velcro patch, and zipper) are available. The key goals are to prevent evisceration, allow swelling of abdominal contents, control peritoneal fluids, prevent contamination, and preserve the fascia for a possible later closure. Ongoing experience with a vacuum-assisted closure technique has provided very promising results. Moreover, use of the vacuum-assisted closure technique has dramatically improved the management of the open abdomen.^{70,71,72}

ANNOTATED REFERENCES

KEY POINTS

1. It is essential to distinguish between intraabdominal hypertension (IAH) and abdominal compartment syndrome (ACS) through the early identification of organ dysfunctions.
2. Intraabdominal pressure (IAP) should be monitored during shock resuscitation requiring ongoing volume loading regardless of the cause of the shock (e.g., burn, sepsis, and trauma).
3. At present, the safest and most feasible method to monitor IAP is the intravesical technique.
4. ACS can occur without abdominal pathology or injury (secondary ACS).
5. To date, the best characterized types of ACS are postinjury ACS, burn-associated ACS, and pancreatitis-associated ACS.
6. Outcomes associated with ACS are very poor even after performing early decompression. Prevention, prediction, and surveillance are the keys to achieve successful management of ACS.
7. Postinjury primary and secondary ACS can be accurately predicted 3-6 hours after hospital admission through adequate monitoring.
8. Awareness of the use of excessive crystalloids during shock resuscitation has decreased the incidence of ACS.
9. Outcomes with open abdomen are improving with the use of vacuum-assisted closure techniques.

Ivy ME, Atweh NA, Palmer J, et al. Intra-abdominal hypertension and abdominal compartment syndrome in burn patients. *J Trauma* 2000;49:387-91.

This is a prospective evaluation of patients with large burns, in whom secondary ACS is a frequent complication. The authors recommend IAP measurements after 0.25 L/kg crystalloid resuscitation and report a high success rate using conservative management of ACS in burn patients.

■ EPIDEMIOLOGY

Compartment syndrome occurs whenever the tissue pressure within a limited space of the body reaches the point where the circulation, nerve function, and muscle function of that space are compromised. For compartment syndrome to occur, the body compartment should be enveloped by fascia that prevents inner tissue expansion, and there should be at least one cause of increased tissue pressure present, either externally or internally.

The German physician Dr. Richard Von Volkmann first described the late sequelae of compartment syndrome in 1881.¹ He wrote: “The paralyzes and contractures that follow tightly applied bandages, chiefly in the forearm and hand, and less often in the lower extremity, are to be viewed as ischemic. They arise from the arterial supply being interrupted for too long.” Volkmann’s ischemic muscle contractures of untreated forearm compartment syndrome are named after him (Fig. 164-1). Later, in 1912, Wilson first described exertional compartment syndrome,^{1a} and Mayor, in 1956, first reported chronic exertional compartment syndrome in a football player.^{1b} Since then, various cases of compartment syndrome have been reported in the literature, and the pathophysiology and treatment options have been discussed. Compartment syndrome has been reported in a wide variety of clinical conditions including tetanus, meningococcemia, malignant hyperthermia, frostbite, horseback riding, and childbirth.²⁻⁶ Typically, it occurs after traumatic events, most commonly those involving fractures or vascular trauma with subsequent ischemia-reperfusion injuries. The most commonly affected body compartments are lower extremity compartments. Recent literature describes an increasing incidence of around 2% in severely injured patients.⁷⁻⁹ This occurs with developments in shock resuscitation in a population of patients with otherwise noninjured extremities. The incidence of compartment syndrome varies depending on the patient population studied and the etiology of the syndrome. In a group of patients with leg pain, according to Qvarfordt and colleagues, 14% were noted to have anterior compartment syndrome.¹⁰ Compartment syndrome was also seen in 1% to 9% of leg fractures.¹¹

Common locations of compartment syndromes are in the upper and lower limbs. The most commonly affected are the four compartments of the lower extremity (anterior, lateral, superficial posterior, and deep posterior), followed by two compartments of the forearm (volar and dorsal). Other compartments that may be affected are the deltoid and biceps compartments of the arm, interosseous compartments of the hand, gluteal compartment of the buttock, quadriceps compartment of the thigh, and interosseous, medial, central, and lateral compartments of the foot.¹²⁻¹⁵

The etiology of compartment syndrome varies and can be divided into three major groups: decreased compartmental volume, increased compartmental content and therefore pressure, and externally applied pressure. There are probably more than 40 causes that fit into one of these groups. Common causes in critical care surgical cases are presented in Table 164-1.¹⁶

The most common causes of compartment syndrome are categorized based on increased compartmental content. The pathophysiologic mechanism of bleeding is easy to understand. Most commonly, bleeding is caused by trauma, but recently, more reports of atraumatic bleeding due to wide use of warfarin, low-molecular weight heparins, or recombinant tissue plasminogen activator (rtPA) have been reported.¹⁷⁻¹⁹

Increasing volume of blood in a space limited by noncompliant fascia results in an exponential rise in intracompartmental pressure. Postischemic swelling or reperfusion injury is more complex since it causes the so-called double ischemic insult. Initial ischemic insult from any cause leads to abnormal function of all tissues including nerves, muscles, and capillaries. This results in abnormalities of neuromuscular function; this is the *first insult*. Increased permeability after the relief of initial ischemia leads to postischemic swelling and subsequently increased compartmental volume and pressure. This leads to the development of compartment syndrome, which causes additional injury to neuromuscular function; this is the *second insult*. This process has clinical consequences. The classic physical examination in patients with reperfusion injury can be unreliable due to loss of motor and nerve function.^{16,20,21}

■ CLINICAL PRESENTATION

Most compartment syndromes in patients who are able to cooperate can be diagnosed by a clinical examination. The most common clinical signs found in the literature are the classic 5 P’s: pain (out of proportion), pulselessness (or weak pulse), pallor, paralysis (numbness and loss of motor function), and pressure (swelling and tenseness of compartment). Occasionally, poikilothermy (cold extremity) is also included (Fig. 164-2, A). These signs are a consequence of increased intracompartmental pressure and loss of various tissue functions. Other signs include skin edema and blisters, swelling, and subcutaneous blood suffusions (see Fig. 164-2, B).

To make the diagnosis, there must first be evidence of increased intracompartmental pressure. If so, these signs do not occur simultaneously but develop with time. One of the first signs is a swollen or tight compartment in combination with severe pain that is out of proportion to the injury and is not relieved by typical analgesia. Other signs present late and often, when present, represent irreversible damage to soft tissues. There are numerous other pathophysiologic events that can cause a similar clinical picture. In fact, a large meta-analysis of studies comparing clinical signs with the development of acute lower extremity compartment syndrome showed a sensitivity of 13% to 19%, specificity of 97%, positive predictive value of 11% to 15%, and negative predictive value of 98%.²² Thus, the absence of this sign rules out compartment syndrome, but the presence rarely confirms the correct diagnosis.

Nevertheless, clinical observation of the suspected compartment is what is recommended since the progress of the symptoms over hours is what should be noted first before making a definitive diagnosis and initiating definitive treatment. In traumatic cases, careful observation is required in open fractures as well. Although early surgery is usually indicated in this group of patients, they can still present with compartment syndrome. One recent animal study has confirmed the necessity of careful monitoring of both open and closed tibial fractures.²³ A useful tool for such monitoring could be a simple sheet with notes about date, time, location, pain level, and motor and sensory testing. To do this, one must know the anatomic position of various compartments and their vascular and nerve content. An example of a simple screening form of the most commonly observed acute lower extremity compartment is shown in Figure 164-3.²⁴ To focus on this relatively rare syndrome and prevent missed diagnoses, more complex systems for monitoring and recognition have been developed in some institutions,

with better recognition and outcomes.²⁵ In order to improve screening in special groups of patients with various etiology are described, where this condition occurs more often. In a large review study, stepwise logistic regression identified the presence of vascular injury, need for PRBC transfusion, male gender, open fracture, elbow or knee dislocation, GSW, ISS greater than or equal to 16, and age less than 55 years as independent predictors for the need for extremity fasciotomy.²⁶ Several statistically significant predictors of relevant compartment syndromes following surgical reperfusion were found, including lactate, uric acid, transcutaneous oxygen pressure, bilirubin, intrafascial pressure, and serum myoglobin.²⁷

■ **DIAGNOSIS**

To make a diagnosis of compartment syndrome, we must have evidence of increased tissue pressure, inadequate tissue perfusion, and loss of tissue function. When all three factors are present, the diagnosis may be made with assurance; when one or more of these factors are absent,

FIGURE 164-2 ■ A, A patient with right lower extremity compartment syndrome due to isolated tibial fracture. On clinical presentation, pain, swelling, and inability of dorsal flexion of the toe were noted. **B,** Another patient with left lower extremity compartment syndrome after popliteal artery tear and revascularization in combination with proximal tibial fracture, was treated with external fixation. A few hours later after initial treatment there are obvious signs of developing compartment syndrome with swelling, skin discoloration, function loss, and fracture blisters.

the diagnosis is less accurate. Evidence of increased tissue pressure may include patient complaints of tightness or pressure in the involved area. By palpation, a physician may perceive tenseness of the compartmental envelope.²⁸

Evidence of inadequate perfusion of local tissue pressure may include the symptom of pain out of proportion to what would be anticipated from the clinical situation. Increasing analgesia requirements in a properly immobilized leg should raise suspicion. Pain on a passive stretch of the intracompartmental muscles is another useful indication of increased pressure, especially if the muscles have not been injured. Reduced peripheral pulses are very late signs of compartment syndrome; in fact, studies have shown normal pulses with Doppler signals in otherwise severely elevated intracompartmental pressures.

FIGURE 164-3 ■ An example of a screening form for acute lower extremity compartment syndrome observation. (Kosir R, Morre FA, Selby LH, et al. Acute lower extremity compartment syndrome (ALECS) screening protocol in critically ill trauma patients. J Trauma. 2007;63:268–275.)

Arterial flow is rarely compromised in elevated tissue compartment pressures. On the other hand, diminished pulses could be a result of other causes (e.g., vascular lesions), and, in combination with reperfusion injury, could also lead to the development of compartment syndrome.²⁸

Evidence of abnormal tissue function includes weakness of the intracompartmental muscles and nerves, including sensory branches, leading to hypoesthesia. Both nerve and muscle function may be altered by direct injury; therefore, evidence of progressive loss of function over time may be a more reliable sign.²⁸

To summarize, in awake and cooperative patients who can be reexamined frequently, the diagnosis of compartment syndrome is associated with the following findings:

1. Pain out of proportion to what is anticipated from the clinical situation
2. Weakness of the muscles in the compartment
3. Pain on a passive stretch of the muscles in the compartment
4. Hypoesthesia in the distribution of the nerves coursing through the compartment
5. Tenseness of the compartmental envelope

Since some clinical signs progress over time, the clinical decision making can be challenging.^{12,30-32} Especially in critically ill patients who are unable to cooperate due to head trauma, sedation, or even neuromuscular blocking drugs, the diagnosis cannot be made based on the clinical examination alone.²⁴ In the pediatric population, compartment syndrome does not always present classically, making clinical diagnosis uniquely challenging.³²

Although the clinical examination should be a cornerstone of the diagnosis of compartment syndrome, it has the disadvantage of being subjective and requiring patient cooperation.^{12,22,33} Therefore, tissue pressure measurement should be performed to assist in establishing a diagnosis so that immediate treatment can be initiated. The normal compartmental interstitial tissue pressure is around 5 mm Hg. Capillary blood flow becomes compromised at 20 mm Hg, and pain develops at pressures between 20 and 30 mm Hg. A tissue pressure of more than 45 mm Hg has been reported to be usually associated with compartment syndrome, and a pressure of more than 60 mm Hg can confirm the diagnosis.³⁴⁻³⁶ However, the tolerance of tissues for increased pressure may be reduced by other factors, such as arterial occlusion, limb elevation, and shock.^{35,37} In these conditions, compartment syndrome may occur at significantly lower interstitial pressures. According to the arteriovenous gradient theory, the local blood flow (LBF) depends on the pressure gradient between arteries (Pa) and veins (Pv) and local vascular resistance to flow (R).

This is described by the formula:

$$\text{LBF} = (\text{Pa} - \text{Pv}) / \text{R}^{38}$$

LBF should be maintained to deliver enough oxygen to the tissues. According to the above relationship, increased resistance that correlates with interstitial pressure is not the only factor that reduces local blood flow. The arterial pressure is also important, whereas venous pressure is somehow related to interstitial pressure. Increasing interstitial pressure also increases venous pressure and furthermore decreases blood flow.

Because tolerance of tissues to increased intracompartmental pressure varies among different individuals and as there are more factors that influence LBF, only one isolated measurement of interstitial pressure may not be enough to diagnose compartment syndrome.³⁹ For example, higher compartment pressures may be necessary before injury occurs to peripheral nerves in patients with systemic hypertension,³⁵ while compartment syndrome may develop at lower pressures in those with hypotension and/or peripheral vascular disease.^{37,40} It has been proposed that the difference between diastolic pressure and intracompartmental pressure is a better marker for compartment syndrome. ΔP is calculated as follows: $\Delta P = \text{DBP (diastolic blood pressure)} - \text{IP (interstitial pressure)}$, and values greater than 30-35 mm Hg suggest compartment syndrome, but a specific threshold does not exist.⁴²⁻⁴⁵

There are numerous methods of tissue pressure measurement.⁴⁶⁻⁴⁹ The most commonly used are commercial handheld pressure monitors (e.g., the Stryker™ device), a simple needle manometer system (Whitesides' technique), and the needle, wick, or slit catheter techniques. The question is accuracy since there are reports that an arterial line manometer is the most accurate device.⁵⁰ The slit catheter, side-ported bevel-tipped needle, or an 18-gauge needle, when appropriately used with current electronic transducer monitoring, may be used clinically with confidence.⁵¹ The arterial line manometer device has an additional advantage of being able to monitor pressure continuously. This is

FIGURE 164-4 ■ Example of pressure measurement in the lower leg. Cross-section shows anatomic compartments and needle placement first in the anterior compartment and then proceeding into the deep posterior compartment. AC, anterior compartment; DPC, deep posterior compartment; PC, peroneal compartment; SPC, superficial posterior compartment.

reported to be useful in tibial diaphyseal fractures, where the estimated sensitivity and specificity of continuous pressure monitoring is high and continuous monitoring should be considered.⁵² Independent of the method used to measure compartment pressures, accuracy depends upon proper calibration of the measuring device and placement of the needle or pressure sensor at the level of the injured compartment. The principle of tissue pressure measurement in the case of acute lower extremity compartment syndrome is shown in Figure 164-4.

Use of near-infrared spectroscopy for detection of low tissue oxygenation and, therefore, the development of compartment syndrome is controversial. It has been reported as a useful noninvasive tool in diagnosing compartment syndrome after surgical revascularization of lower limb ischemia and also in traumatically injured patients; subsequent studies did not prove its utility in injuries due to severe edema of the soft tissues, and it cannot measure Sto_2 inside the muscle compartment.^{30,44,53-60}

In recent animal research, the role of intramuscular glucose and partial pressure of oxygen for detecting compartment syndrome has been evaluated. Intramuscular glucose concentration and partial pressure of oxygen measured with commercially available probes rapidly identified muscle ischemia with a high sensitivity and specificity after an experimentally induced compartment syndrome in an animal model.⁶²

In establishing a diagnosis of compartment syndrome, other causes of pain-producing symptoms have to be ruled out or confirmed, or a cause of elevated intracompartmental pressure should be determined. When facing traumatic injuries, a workup for rhabdomyolysis (creatinine phosphokinase [CPK], renal functions, urinalysis, and urine myoglobin) should be considered. In a group of patients with tibial fractures with or without compartment syndrome, a model combining maximal CPK level greater than 4000 U/L, maximal chloride level greater than 104 mg/dL, and minimal BUN level less than 10 mg/dL had a 100% association with compartment syndrome (CS).⁶³ Extremity x-ray or CT scans can confirm the presence of a fracture. MRI or

ultrasonography can show muscle tears. Doppler ultrasonography or arteriography can detect vascular abnormalities.

MANAGEMENT

The objective of treatment of compartment syndrome is to minimize deficits in muscular and neurologic function by promptly restoring LBF. Certain nonoperative measures may be effective, such as eliminating external pressure and maintaining local arterial pressure. When there is external pressure that causes compartment syndrome, such as tight casts, it is essential to release the envelope immediately (remove and exchange for a noncircular splint) when there is only one symptom or sign present. Usually, this is pain and is most often observed in patients with fracture splints several hours after treatment. Restoration of normal limb perfusion has priority over closed fracture treatment, and this can be postponed until perfusion returns to normal. Prior to resorting to operative methods for reducing tissue pressure, it is important to consider improvement of LBF if it has been reduced by shock, peripheral vascular disease, or elevation of the limb above the heart. All causes of systemic hypotension should be treated. Limb elevation should be avoided because it lowers local arterial pressure and does not help in reducing swelling.⁶⁴ Use of vasodilating drugs or sympathetic blockade appears to be ineffective because, in this condition, local maximal vasodilatation is already present. The use of phosphodiesterase inhibitors in experimental animal models caused modulation of compartmental pressures.⁶⁵ In a large study on trauma patients with isolated arterial injury, early anticoagulation with heparin was found to reduce the incidence of compartment syndrome without significant bleeding as a consequence.⁶⁶ Carbon monoxide-releasing molecule-3 displays a potent protective/antiinflammatory action in an experimental model of compartment syndrome, suggesting a potential therapeutic application for patients at risk of developing compartment syndrome.⁶⁷

The primary goal of treating compartment syndrome is to decrease intracompartmental pressures. Surgical decompression of all limiting envelopes is the gold standard of treatment, indicated in the presence of a characteristic clinical picture of compartment syndrome in a cooperative patient. When the clinical examination is unreliable or difficult to obtain, pressure measurement should be obtained, where either pressure should not exceed 45 mm Hg or ΔP should not be below 30 mm Hg.

Standard treatment involves a long skin incision and fasciotomy of all involved compartments and debridement of obvious nonviable tissue. Usually, this procedure is performed under general or spinal anesthesia. Bedside fasciotomy under local anesthesia has been described in select cases to be feasible and reliable.⁶⁸ Fasciotomy should be performed without a tourniquet to avoid prolonging ischemia and to permit the surgeon to assess the degree of viability and restoration of blood flow. The skin is incised through the entire length of the involved compartment. There is obvious muscle bulging observed in true compartment syndrome (Fig. 164-5). Only obvious necrotic muscle should be removed because the tissue may have the potential for reperfusion and recovery. The sign of contractility with electrostimulation should not be used initially. After fascial release, postischemic swelling should be anticipated; therefore, the skin should be left open and the wound temporarily closed with a patch of compliant artificial temporary skin closures. If release of the compartment is not complete, “rebound” compartment syndrome may occur.

After surgical decompression and temporary skin closure, sterile dressings are applied and the extremity is usually splinted in a functional position. In the presence of fractures, one should consider fixation with external fixators, rarely with plates or intramedullary nails. This stabilization is performed immediately after fascial decompression and greatly facilitates later care of the wound, limb, and fracture. Passive stretching exercises are performed to maintain range of joint motion. Skin closure may usually be performed 3-5 days after surgical decompression, usually by a mesh graft and rarely by direct suturing (Fig. 164-6). At that time, additional debridement of nonviable tissue can be performed. Fascial closure is not recommended because this

FIGURE 164-5 ■ The patient in Figure 164-2A after fasciotomy of the anterior and peroneal compartment and external fixation of the tibial fracture. Note obvious muscle bulging after release of fascial compartments. Direct skin closure was not possible.

FIGURE 164-6 ■ Cosmetic result of the lower extremity compartment syndrome after mesh grafting of the lateral compartment.

requires closure under tension and can lead to re-development of compartment syndrome. Muscle hernia is left behind and should be large enough to not cause additional late problems. When an optimal cosmetic result is desired, one may progressively approximate the wound edges over 7-14 days with sutures to achieve direct skin closure.

Negative pressure wound care closure devices can be useful in the management of fasciotomy wounds. Negative pressure decreases wound edema, facilitates approximation of the skin edges, enhances LBF, promotes granulation tissue, and decreases bacterial colonization. Conversely, in one animal study, negative pressure may be harmful to skeletal muscle after compartment syndrome.⁶⁹ One recent randomized study compared vacuum-assisted closure (VAC[®]) with the shoelace technique. Both techniques were safe, reliable, and effective methods for closure of leg fasciotomy wounds. VAC[®] required a longer time for definite wound closure and was reported to be far more expensive than the shoelace technique, especially when additional skin grafting was required.⁷⁰ In retrospective analyses, negative pressure led to significantly higher rates of complete skin closure and decreased time to skin closure.^{71,72} Hyperbaric oxygen as an adjunct to management following fasciotomy is reported in some case reports and animal studies, but there is a lack of evidence suggesting that this is advantageous over current practices.⁷³⁻⁷⁷

FASCIOTOMY

Fasciotomy depends on the underlying condition or mechanism that caused compartment syndrome. The length of the lower extremity skin incisions has been debated for a long time. Minimal skin incisions with more extensive fascial incisions could place the patient at risk of recurrent compartment syndrome.⁷⁸⁻⁸⁰ The degree of muscle swelling after reperfusion cannot be predicted, and peak edema occurs several hours after surgery.

Fasciotomy of the Upper Extremity

The upper extremity is anatomically divided into the brachium, antebrachium, and hand. Each of the anatomic segments has a different number of compartments with various muscle functions. Techniques for release of these compartments have to be discussed separately, and combined fasciotomy is shown in [Figure 164-7](#).

Fasciotomy of the Brachium

The arm has two compartments: anterior, which includes biceps and brachioradialis muscles, and posterior with the triceps muscle. Fasciotomy includes a lateral skin incision from the deltoid insertion to the lateral epicondyle. Care must be taken to avoid damage to the larger cutaneous nerves. At the fascial level, the intermuscular septum between the anterior and posterior compartments is identified, and fascia overlying each compartment is released with longitudinal incisions. The radial nerve should be protected as it passes through the intermuscular septum from the posterior compartment to the anterior compartment just below the fascia (see [Fig. 164-7](#)).

FIGURE 164-7 ■ Clinical photographs of combined fasciotomy of the upper extremity. Dorsal and volar aspects.

Fasciotomy of the Antebrachium

The antebrachium has three muscular compartments: mobile wad proximally, volar compartment, and dorsal compartment. Fasciotomy consists of a longitudinal, centrally placed incision over the extensor compartment and a curvilinear incision on the flexor aspect beginning at the antecubital fossa ([Fig. 164-8](#)). A palmar incision is made between the thenar and hypothenar muscles in the palm, where the carpal tunnel can be released if needed. The incision is extended transversely across the wrist flexion crease to the ulnar side of the wrist and then arched across the volar forearm back to the ulnar side at the elbow. At the elbow, the incision is curved just radially to the medial epicondyle across the elbow flexion crease, and the deep fascia is released. At the antecubital fossa, a fibrous band overlying the brachial artery and median nerve is carefully released. This incision allows for soft tissue coverage of underlying neurovascular structures at the wrist and elbow and prevents soft tissue contractures from developing at flexion creases. A second straight dorsal incision can be made to release the mobile wad if necessary.

Fasciotomy of the Hand

The hand has a unique anatomy with 10 separate fascial compartments: 4 dorsal and 3 volar interossei, thenar muscles, hypothenar muscles, and the adductor pollicis muscle. Fasciotomy consists of four incisions ([Fig. 164-9](#)). One incision on the radial side of the thumb metacarpal releases the thenar compartment. A dorsal incision over the index finger metacarpal is used to release the first and second dorsal interossei, to reach the ulnar-to-index finger metacarpal, and to release the volar interossei and adductor pollicis muscle. A dorsal incision over the ring finger metacarpal is used to release the third and fourth dorsal interossei and to reach down along the radial aspect of the ring finger and small finger metatarsal to release volar interossei. An incision placed at the ulnar aspect of the small finger is used to release the hypothenar muscles.

Fasciotomy of the Lower Extremity

The lower extremity is anatomically divided into three parts: thigh, lower leg, and foot. As in the upper extremity, each anatomic segment has a different number of compartments with various muscle functions. Techniques for release of these compartments are discussed separately as well.

Fasciotomy of the Thigh

The thigh has three compartments: anterior (quadriceps), medial (adductors), and posterior (hamstrings) (Fig. 164-10). Because of the large potential volume, compartment syndrome and blending of fascial compartments with the hip (allows extravasation of blood outside compartments) in the thigh are less likely to occur but can be seen especially in patients with high-energy femoral fractures or hip fractures. Fasciotomy consists of lateral incisions made from the greater trochanter to the lateral condyle of the femur. The iliotibial band is incised, and the vastus lateralis is reflected off the intermuscular septum bluntly, thereby releasing the anterior compartment. The intermuscular septum is then incised over the length of the incision, releasing the posterior compartment. This release should not be done close to the femur since a series of perforating vessels pass through the septum posteriorly to anteriorly near the bone. The medial compartment is released through separate anteromedial incisions (Fig. 164-11).

Fasciotomy of the Lower Leg

Lower extremity compartment syndrome is the most common due to the unique anatomy of compartments. Most of the studies on compartment syndrome have been conducted on this part of the body, and most of the current knowledge about epidemiology and treatment is based on lower extremity compartment syndrome studies. The lower leg has four compartments: lateral (peroneal brevis and longus), anterior (extensor hallucis longus muscle, extensor digitorum longus muscle, tibialis anterior muscle, and peroneus tertius), superficial posterior (gastrocnemius and soleus), and deep posterior (flexor hallucis longus muscle, flexor digitorum longus muscle, and tibialis posterior muscle) (Fig. 164-12). The anterior compartment is the most commonly involved, followed by the deep posterior compartment. In the case of compartment syndrome of any of the compartments, release of all four is recommended.

There are two surgical techniques for release of all four compartments in the lower leg: one-incision technique (Fig. 164-13) and

FIGURE 164-10 ■ Anatomy of the compartments of the thigh. (From Standing S, et al., editors, Gray's Anatomy, 40th ed. Edinburgh, Churchill Livingstone, 2008.)

FIGURE 164-11 ■ Schematic presentation of fasciotomy of the thigh. (From Wheeless CR. Wheeless' Textbook of Orthopaedics. Towson, MD: Data Trace, 2014. © 2010, Damian Rispoli, MD.)

two-incision technique (Fig. 164-14). There is no strong evidence on which technique has an advantage over the other. The only retrospective study in the setting of tibial fractures comparing the two methods found similar infection and nonunion rates.⁸¹ The one-incision technique resulted in only one surgical wound and fewer related complications in one study.⁸² It seems that the choice for fasciotomy can be based on surgeon experience, and, due to simplicity, the two-incision technique is more often used.

One-Incision Technique

The one-incision technique is technically more difficult as it is difficult to visualize the deep posterior compartment, and therefore, there is an increased risk of injury to the peroneal artery and nerve. The technique starts with a skin incision 1 to 2 cm anterior and parallel to the fibula, just inferior to the fibular head and 3 to 4 cm proximal to the lateral malleolus. An anterior flap enables exposure of the anterior and lateral compartments. Longitudinal incisions are made in the fascia, and care must be taken to avoid damage to the common, superficial, and deep peroneal nerves at the fibular head. A lateral flap is exposed more posteriorly to visualize the superficial posterior compartment. The gastrocnemius muscle should be identified, and the fascia is incised longitudinally. The deep posterior compartment is identified later,

FIGURE 164-12 ■ Anatomy of the compartments of the lower leg. (From Black JM, Hawks JH. Medical-Surgical Nursing, 8th ed. Philadelphia: Saunders, 2009.)

FIGURE 164-13 ■ Single-incision fasciotomy of the lower leg.

A, Lateral skin incision from the fibular neck to 3 to 4 cm proximal to the lateral malleolus. **B,** The skin is undermined anteriorly, and a fasciotomy of the anterior and lateral compartments is performed. **C,** The skin is undermined posteriorly, and a fasciotomy of the superficial posterior compartment is performed. **D,** An interval between the superficial posterior and lateral compartments is developed. The flexor hallucis longus muscle is dissected subperiosteally off the fibula and retracted posteromedially. The fascial attachment of the posterior tibial muscle to the fibula is incised to decompress the muscle. (From Davey JR, Rorabeck CH, Fowler PJ. The tibialis posterior muscle compartment: an unrecognized cause of exertional compartment syndrome. *Am J Sports Med* 1984;12:391–397.)

after exposure of the posterior side of the fibula with dissection of the soleus muscle. Fasciotomy of the deep posterior compartment is performed at the medial border of the fibula. Here, peroneal vessels should be retracted and protected posteriorly to avoid injury (see Fig. 164-13).

Two-Incision Technique

This technique uses medial and lateral longitudinal incisions that should be long enough to completely release all four compartments. In adults, incisions can be up to 30 cm long. The lateral incision starts about 5 cm lateral to the anterior border of the tibia. Underlying the incision are the fascial tissues of the anterior and peroneal compartments; these are identified and released. The intermuscular septum should be identified to ensure that both compartments are released. Care must be taken to not damage the common peroneal nerve proximally as it passes around the fibular head; therefore, skin incisions should not reach the fibular head level. Distally, the skin incision ends about 5 cm above the lateral malleolus. The medial incision of the two-incision technique starts 2 cm medial to the tibial margin. It is used to release both posterior compartments. Care must be taken to avoid saphenous nerve and vein damage, and these structures should be identified prior to fasciotomy of these compartments. The superficial posterior compartment is decompressed by incising the gastrocnemius fascia in a longitudinal direction proximally to distally. The posterior compartment is decompressed by dividing the attachments of the soleus muscle to the tibia (see Fig. 164-14).

Fasciotomy of the Foot

Acute compartment syndrome of the foot most commonly occurs due to crush injury, and fasciotomy is rarely needed. There are four major compartments of the foot: intraosseous, lateral, central (calcaneal), and medial (Fig. 164-15). They are further divided into smaller muscle groups, so there are nine compartments in the foot, but this number is controversial (Fig. 164-16). Whereas each of the compartments should generally be released, some debate exists whether the superficial compartment of the dorsal central compartment, which contains the flexor digitorum brevis muscle, should be included. A dorsal approach is most commonly used and requires less dissection than the other two. It begins with dual dorsal longitudinal incisions over the medial side of the second metatarsal bone and the lateral side of the fourth metatarsal bone. Each of the four interosseous compartments is released first between the metatarsal bones. The medial compartment may be released by accessing a space medial to the second metatarsal; the

FIGURE 164-14 ■ Two-incision technique for fasciotomy of the lower leg. (A) A cross-sectional view and (B) position of skin incisions. Both wounds have been temporarily covered with an artificial skin graft. (A, from Cameron JL, Cameron AM. *Current Surgical Therapy*, 10th ed. Philadelphia: Saunders, 2011.)

FIGURE 164-15 ■ Compartments of the foot. (From Twaddle BC, Amendola A. *Compartment syndromes*. In: Browner BD, Jupiter JB, Levine AM, et al., editors. *Skeletal Trauma*, 4th ed. Philadelphia: Saunders, 2009.)

lateral compartment is released by accessing a space lateral to the fourth metatarsal bone. The calcaneal compartment lies underneath the second interosseous space and can be released through a medial incision. The superficial compartment is accessed through the calcaneal compartment by blunt dissection of the adductor hallucis muscle. Sometimes release of this compartment is not required, since it contains predominantly tendons of the finger flexors and is not a “true” muscular compartment.

POTENTIAL COMPLICATIONS

Delay of treatment of compartment syndrome can lead to irreversible complications and, left untreated, can lead to death. The initial management should be focused not only on preservation of tissue viability in the compartment but also on the initial management of systemic complications of reperfusion injury. This requires restoration of intravascular volume, prevention of hyperkalemia, and treatment of metabolic acidosis and myoglobinuria, which may lead to acute

FIGURE 164-16 ■ Fasciotomy of the foot. Medial and dorsal approaches. (From Banerjee R, Nickisch F, Easley ME, DiGiovanni CW. *Foot injuries*. In: Browner BD, Jupiter JB, Levine AM, et al., editors. *Skeletal Trauma*, 4th ed. Philadelphia: Saunders, 2009.)

kidney injury. Complications may also occur as a sequela of surgical procedures performed and wound management. Late sequelae of compartment syndrome include persistent hypoesthesia, dysesthesia, persistent motor weakness, infection, myoglobinuric renal failure, contractures, amputation, and death. In one study, persistent sequelae are reported to be associated with a higher number of operations, post-fasciotomy complications, closures with skin grafting, and increased time to closure.⁸³

Technical complications of fasciotomy are preventable when considering the anatomy of important structures. Persistent or recurrent compartment syndrome can occur if fascial incisions are not adequate to permit complete decompression of the compartment or if selective fasciotomy has been performed.⁷⁸

Persistent neurologic deficits following fasciotomy are common. Nerve injury can occur due to the initial traumatic event, prolonged ischemia, or as a consequence of fasciotomy dissection and tissue

débridement. The most common neuropathic syndrome is altered sensation at the margins of the incision; chronic pain syndromes are also described.⁸⁴ Impaired neurologic function after lower extremity fasciotomy is described in 7% to 36% of injured limbs.⁸⁵⁻⁸⁷

Wound complications after fasciotomy may occur immediately or be delayed for months to years. Early wound complications occur in up to 40% of patients following lower extremity fasciotomy.^{85,88,89} Risk factors are related to the presence of vascular injury, lower extremity site, and premature or delayed closure of the wound.⁸⁹ Wound infection occurs in 4% to 7% of extremity fasciotomies.^{85,88} Prophylactic antibiotics should be given at the time of fasciotomy and discontinued after 24 hours. Repeated débridement of devitalized tissue may protect from severe wound infections and sepsis. Late wound complications are reported in 4% to 38% of limbs.^{84,85,88,89} Delayed wound complications include tethered scars and tendons, muscle hernias, and poor healing and ulceration, especially in patients with underlying vascular diseases. Venous insufficiency can predispose patients to chronic venous disease after fasciotomy. Tibial diaphyseal fracture healing in patients with compartment syndrome has been found to be delayed, and the rates of nonunion are reported to be higher compared with patients without compartment syndrome.⁹⁰

Acute extremity compartment syndrome is associated with significant risk of limb loss.⁹¹ Major amputation will be required in 5% to 21% of limbs treated with fasciotomy.^{85,86,88,89,91} Combined orthopedic and vascular injury, other severe injuries, and systemic factors may contribute to the need for amputation in severely injured patients. The highest amputation rate occurs in patients with severe vascular injuries with occlusion.⁸⁵ A large review of the National Trauma Data Bank for lower extremity vascular injury comparing early versus late fasciotomy findings suggests that appropriate implementation of early fasciotomy may reduce amputation rates.⁹² Amputation of the upper extremity following fasciotomy is rare.

The most severe cases of compartment syndrome left untreated may cause death. Reported mortality ranges from 11% to 25% and depends on the epidemiology of the compartment syndrome.^{78,86,88,93} Mortality is most often due to massive trauma, severe hypovolemic shock, and multisystem organ failure and cannot be attributed only to the need for fasciotomy. This is especially true in severely injured patients with massive shock resuscitation where the mortality after fasciotomy in one study reached 67%.²⁴

CONCLUSION

The patient who undergoes fasciotomy requires a physical therapy program to regain function. Postoperative care and rehabilitation

are just as important as the procedure itself. During the immediate postoperative period, weight bearing is limited, and assistive devices (e.g., crutches) are needed. Within a few days, and with adequate pain control, the use of crutches can be discontinued. The rehabilitation program then involves range of motion (ROM) and flexibility exercises involving the muscles of the affected compartment. Adjacent joints need to be exercised to maintain their normal ROM.

Once the patient is able to ambulate with a normalized gait pattern, a program of graduated resistive exercises (depending on the patient's regular activities or work) is initiated. In the case of athletes, sports-specific exercises are started with the intention of returning to a regular athletic schedule. Cross training is also beneficial for these athletes. Activities such as swimming, pedal exercises, water jogging, or running help athletes regain muscle strength and flexibility without loading the affected compartment.

With surgical intervention for decompression, occupational therapy consultation should be considered early in the postoperative period. Appropriate treatment and assessment of the patient's deficits with regard to activities of daily living, as well as for instruction in the use of any necessary assisted devices should be assessed.

KEY POINTS

1. Compartment syndrome is a life-threatening condition and should be treated as soon as it is diagnosed.¹⁶
2. One of the first signs of compartment syndrome is a swollen extremity with pain out of proportion and increasing requirements for analgesia.^{12,28,30-32}
3. Critically ill patients, especially after severe trauma with massive fluid resuscitation, require special attention and frequent evaluation.²⁴
4. Diagnosis of compartment syndrome is very likely when intracompartmental pressure reaches 45 mm Hg or the difference between diastolic blood pressure and intracompartmental pressure is less than 30 mm Hg.^{34-36,38,42-45}
5. Treatment of compartment syndrome is primarily surgical with prompt release of muscle compartments by fasciotomy.⁶⁴⁻⁶⁸

Thrombolytic agents comprise a diverse group of compounds that indirectly initiate the lysis of a thrombus. After the initiation of a coagulation cascade, fibrinolytic mechanisms are concomitantly activated to prevent unconstrained thrombosis. Fibrinolysis begins with the cleavage of proenzyme plasminogen to plasmin, which hydrolyzes key bonds within a fibrin clot matrix, resulting in clot lysis (Fig. 165-1). Thrombolytic agents function by converting plasminogen to plasmin. Different thrombolytic agents vary in their specificity for plasminogen, metabolic half-life, and antigenicity (Table 165-1).

■ DRUGS

Streptokinase

Streptokinase, a protein produced by beta-hemolytic streptococci, was identified as having fibrinolytic properties in the 1930s¹ and was the first compound to be used clinically as a thrombolytic drug.² Streptokinase complexes with plasminogen and converts it to plasmin. However, one of the major drawbacks of using streptokinase is its antigenicity because streptococcal infection may induce antibody formation. Mild allergic reactions occur in 2% to 5% patients; however, severe anaphylactic reactions may also occur.³

Urokinase

Urokinase is a thrombolytic protein that was initially isolated from human urine and has been used clinically for over 30 years. At present, it is isolated from human fetal renal tissue cultures. Unlike streptokinase, urokinase enzymatically cleaves plasminogen. In 1999, urokinase was removed from the U.S. market after concerns raised by the Food and Drug Administration (FDA) regarding its safety.⁴ It was reintroduced in the United States in 2002 after rigorous testing showed that urokinase preparations were free of human pathogens. However, at present, it is only approved for treating pulmonary embolism (PE). Prourokinase (also known as single-chain urokinase-type plasminogen activator) is a single-chain precursor of urokinase that is converted into two-chain urokinase by hydrolysis.

Tissue Plasminogen Activator

Tissue plasminogen activator (t-PA), which was first isolated in 1981,⁵ is a naturally occurring protein synthesized by human vascular endothelial cells. Several recombinant variants of t-PA are available, including alteplase (rt-PA, approved by the FDA in 1987) and duteplase. Other forms of tissue-type t-PAs include reteplase (r-PA), tenecteplase (TNK-tPA), and lanoteplase (n-PA). Recombinant t-PAs are nonantigenic and show specificity for fibrin-bound plasminogen. They also avoid the infectious risks associated with products isolated from cultured human tissues. Newer recombinant t-PAs have improved pharmacokinetics that enables their convenient administration such as bolus dosage.

Other Agents

Other compounds that have been developed and investigated include vampire bat plasminogen activator (isolated from the saliva of vampire

bat), fibrolase (isolated from the venom of southern copperhead snake), and staphylokinase (isolated from *Staphylococcus aureus*). However, data on these compounds are relatively limited; hence, they are rarely used clinically.

■ CLINICAL INDICATIONS

Myocardial Infarction

Acute myocardial infarction (AMI) is associated with a significant health care burden in industrialized countries. Modern management of AMI focuses on rapidly restoring perfusion to optimize myocardial salvage. Primary percutaneous coronary interventions are superior to thrombolytic therapy when employed as an early reperfusion strategy after AMI and are the first-line therapy.⁶ However, logistic barriers hinder the access of patients with AMI who require interventional cardiology services to early percutaneous coronary intervention (PCI). On the other hand, fibrinolytics are administered in almost all hospitals.

Lytic therapy was first used for treating AMI in the 1950s.⁷ Fibrinolytic Therapy Trialists' Collaborative Group performed a meta-analysis by using results obtained from over 58,000 patients treated with thrombolytics.⁸ This meta-analysis showed that treatment with thrombolytics resulted in approximately 25% reduction in mortality in patients with ST-segment elevation or bundle branch block. Since then, numerous studies have evaluated the efficacies, dosage strategies, administration routes of different lytic agents, and adjunctive therapies with these agents for rapidly restoring blood flow in thrombosed coronary arteries.

Early studies such as ISIS-2³ and GISSI⁹ focused on the use of streptokinase and showed 18% and 25% reduction in mortality after 3 and 5 weeks, respectively. Similar results were obtained after 1- to 10-year follow-up.¹⁰ The efficacy of t-PA was studied in the GUSTO-1 trial, which examined four dosing regimens for the treatment of MI in 41,021 patients.¹¹ This study used "accelerated" t-PA dosage in which two-thirds of the total dose was administered in the first 30 minutes rather than over a 3-hour period. This dosage regimen resulted in a modest but significant reduction in 30-day mortality (6.3%) compared with streptokinase (7.4%) or a combination of t-PA and streptokinase (7.0%). The GUSTO angiographic substudy showed that differing patency rates among patients treated with either agent accounted for this difference in clinical efficacy. However, a subsequent meta-analysis of this approach failed to validate the survival advantage.¹²

Newer generation t-PAs such as r-PA and TNK-tPA can be used to administer bolus dosage. The GUSTO III trial compared reteplase, the recombinant deletion mutant of t-PA, with accelerated t-PA in 15,059 patients. This trial did not detect any survival advantage with r-PA and showed that rates of intracranial hemorrhage (ICH) were similar after treatment with r-PA and t-PA (0.91% and 0.87%, respectively).¹³ The ASSENT-2 trial showed that 30-day mortality and ICH rates were identical in patients treated with TNK-tPA and those treated with accelerated t-PA.¹⁴ Although r-PA and TNK-tPA are not superior to t-PA in terms of safety and efficacy, their pharmacokinetics allow simplified administration compared with that of accelerated t-PA.

Adjunctive therapies such as aspirin, clopidogrel, and antithrombin agents improve the results of lytic therapy. Fibrinolysis strips fibrin

| Plasminogen binding | Indirect | Direct | Direct |

from an occluding thrombus; the exposed thrombin then initiates platelet aggregation and subsequent rethrombosis.¹⁵ Heparin is typically used to maintain activated partial thromboplastin time (aPTT) between 50 and 70 seconds. If heparin-induced thrombocytopenia is suspected, then direct thrombin inhibitors such as hirudin or bivalirudin are viable options.¹⁶ Another development is the introduction of glycoprotein IIb/IIIa receptor blockers such as abciximab (ReoPro), eptifibatide (Integrilin), and tirofiban (Aggrastat).¹⁷⁻¹⁹ Despite some promising early results,²⁰ no randomized trial has yet shown the effect of these agents on mortality.²¹⁻²³ A meta-analysis of 11 randomized trials assessing thrombolytic treatment with and without abciximab suggested a significantly increased risk of major bleeding events (5.2% vs. 3.1%, $P < 0.001$) with abciximab.²⁴

The timing of diagnosis and institution of thrombolytic therapy is critical.^{25,26} Patients with AMI who are treated with thrombolytic agents at more than 4 hours after symptom onset have 2 to 3 times higher 30-day and 6-month mortality rates than patients treated within 2 hours of symptom onset.²⁷ The Late Assessment of Thrombolytic Efficacy study reported 1-year mortality rates of 17.6% and 15.8% in patients treated with rt-PA at greater than 3 hours and less than

3 hours, respectively, after symptom onset.²⁸ Therefore, prehospital administration of thrombolytics is recommended in select patients showing ST-segment elevation on electrocardiogram.^{29,30}

The currently accepted guidelines for lytic therapy of AMI are outlined by the American College of Chest Physicians in the 8th edition (2008) of Evidence-Based Clinical Practice Guidelines and by the American College of Cardiology/American Heart Association in their 2013 guidelines.^{31,32} A treatment algorithm for AMI is shown in Figure 165-2. The established guidelines indicate that patients who are most likely to benefit from fibrinolytic therapy are those with ST-segment elevation, symptoms that began within 3 hours, anticipated delay to reach PCI facility, and low bleeding risk. However, the value of thrombolytic agents for managing unstable angina remains unproven thus far. At present, lytic therapy is not used for treating acute coronary syndrome without ST-segment elevation in two or more contiguous leads or without new-onset bundle branch block. Contraindications to lytic therapy in the setting of AMI are summarized in Table 165-2.

Since the development of thrombolytics, coronary angioplasty has become the gold standard for treating MI with ST-segment elevation.

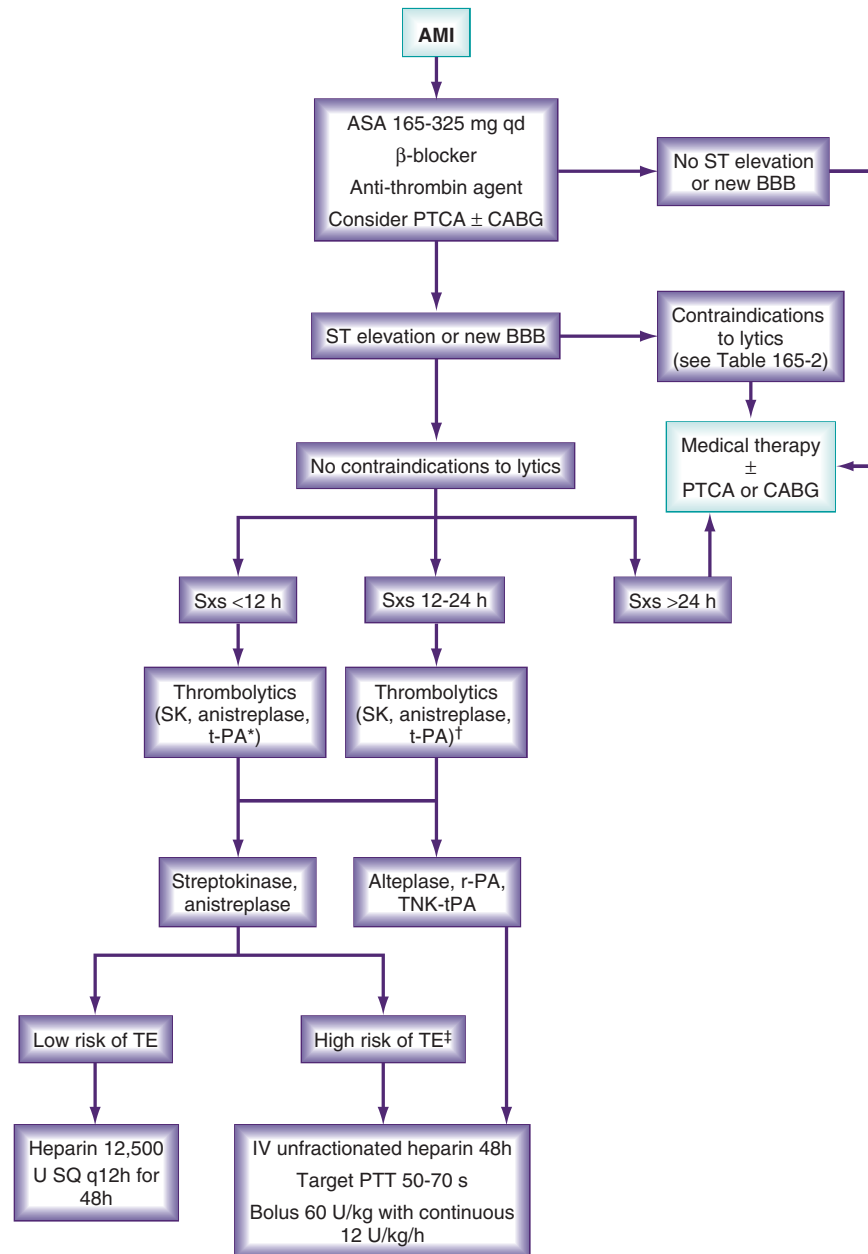

FIGURE 165-2 ■ Algorithm for treating acute myocardial infarction.*Preferred for symptom duration of <6 hours; †grade 2b data¹¹; ‡anterior myocardial infarction, existing heart failure, previous embolus, atrial fibrillation and left ventricular thrombus. AMI, acute myocardial infarction; BBB, bundle branch block; PTCA, percutaneous transluminal coronary angioplasty; CABG, coronary artery bypass grafting; Sxs, signs and symptoms; PTT, partial thromboplastin time; SK, streptokinase; SQ, subcutaneous; TE, thromboembolism. (Data from 1999/2002 ACC/AHA Guideline Update and 2001 ACCP Consensus Conference.¹¹⁻¹²)

A large meta-analysis of 7739 patients with ST-segment elevation who were randomized to receive thrombolytic therapy (76% receiving fibrin-specific lytics) or primary percutaneous transluminal coronary angioplasty (PTCA)⁶ showed that short-term (4- to 6-week) mortality in patients in the PTCA group was 7% compared to 9% in patients in the lytic therapy group ($P = 0.0003$). Patients treated with primary PTCA showed lower rates of nonfatal reinfarction (3% vs. 7%) and stroke (1% vs. 2%) during follow-up in a smaller study.³³ Short-term results of this meta-analysis are summarized in Fig. 165-3.

Potential advantages of angioplasty over thrombolysis³⁴⁻³⁷ as the primary therapy for AMI are tempered by the recognition that results

of angioplasty are highly dependent on the volume of cases at a given treatment center. Moreover, many patients initially present to facilities where interventional cardiology services are not available for performing PCI, resulting in the use of thrombolytics before performing PCI. The recent Strategic Reperfusion Early After Myocardial infarction (STREAM) trial showed that fibrinolytic therapy, clopidogrel, and enoxaparin followed by PCI exerted beneficial effects compared with primary PCI in patients with MI associated with ST-segment elevation who were unable to undergo PCI within 1 hour.³⁸ Moreover, the Trial of Routine Angioplasty and Stenting after Fibrinolysis to Enhance Reperfusion in Acute Myocardial Infarction (TRANSFER-AMI) trial

TABLE 165-2

Contraindications to Thrombolytic Therapy in the Setting of Acute Myocardial Infarction (With ST-Segment Elevation and/or New Bundle Branch Block)

| ABSOLUTE CONTRAINDICATIONS | RELATIVE CONTRAINDICATIONS |
|--|---|
| >24 hours since symptom onset | 12 to 24 hours since symptom onset |
| Prior intracranial hemorrhage | Age >75 years |
| Stroke within the past year | Systolic blood pressure of >180 mm Hg or diastolic blood pressure of >110 mm Hg |
| Intracranial neoplasm | Bleeding disorder |
| Active bleeding/bleeding diathesis | Prior allergic reaction to thrombolytics |
| Suspected aortic dissection | Pregnant or lactating |
| Significant closed-head or facial trauma within 3 months | Prolonged cardiopulmonary resuscitation (>10 min) |
| | Recent internal bleeding (less than 2-4 weeks) |
| | Active peptic ulcer |

FIGURE 165-3 ■ Short-term clinical outcomes in patients treated with percutaneous transluminal coronary angioplasty and those treated with thrombolytic therapy. Odds ratios with 95% confidence intervals. (Reprinted with permission from Keeley EC, Boura JA, Grines CL. Primary angioplasty versus intravenous thrombolytic therapy for acute myocardial infarction: a quantitative review of 23 randomised trials. *Lancet* 2003;361:13-20.)

showed a reduction in the composite endpoint of death, reinfarction, recurrent ischemia, new or worsened congestive heart failure, or cardiogenic shock within 30 days (11.0% vs. 17.2%; OR, 0.64; 95% CI, 0.47-0.87) in patients treated with early (<6 hours) PCI after thrombolytic therapy compared with those treated with standard therapy.³⁹ The ideal treatment for some patients may involve a combination of thrombolytic therapy, antithrombotic agents, antiplatelet agents and PCI.

Stroke

Stroke is the third leading cause of death in the United States, affecting over 700,000 people per year. The majority of strokes are ischemic and result from sudden occlusion of arteries that deliver blood to the brain.

Traditional therapy for ischemic stroke includes anticoagulant and antiplatelet agents for medical support, followed by rehabilitation after the acute event. More recently, thrombolysis has emerged as a treatment for ischemic stroke. Similar to that for AMI, the efficacy of thrombolysis for treating stroke is highly time dependent because of the characteristics of ischemic penumbra⁴⁰ and is the highest when lytic treatment is initiated within 90 minutes after symptom onset.⁴¹

Use of clot-busting therapies for ischemic stroke dates back to 1995 when the National Institute of Neurological Disorders and Stroke (NINDS) published a study on rt-PA for treating acute ischemic stroke.⁴² The trial examined the clinical efficacy of intravenous (IV) t-PA administered within 3 hours of symptom onset. Administration of t-PA did not improve neurologic function at 24 hours compared with administration of placebo. However, in the long term, patients who received t-PA were 30% more likely to have minimal residual disability or were more likely to return to baseline functional status after 3, 6, and 12 months.⁴³ However, patients treated with t-PA showed higher incidence of intracerebral hemorrhage (6.4% vs. 0.6%, $P < 0.001$) at 36 hours. Nevertheless, mortality at 3 months was not significantly different (17% vs. 21%, $P = 0.30$). The results of this study led to the approval of IV t-PA by the FDA for treating acute ischemic stroke within 3 hours of symptom onset.

Other early randomized trials on IV t-PA for treating acute stroke were the European Cooperative Acute Stroke Study (ECASS-I),⁴⁴ ECASS-II,⁴⁵ and ATLANTIS trials.^{40,46} Although these trials did not reach significance for their primary outcome measure, they did show a significant benefit of using t-PA within 0 to 6 hours of symptom onset for improving alternative outcome measures, thus supporting its clinical use. More recently, the ECASS-III trial showed a significant but modest benefit of t-PA compared with that of placebo when administered within 3 to 4.5 hours of symptom onset, with no difference in mortality.⁴⁷ Based on the results of this trial, Lansberg et al. calculated the number of patients deriving benefit per 100 treated as 28, 23, and 17 for the 0- to 1.5-, 1.5- to 3-, and 3- to 4.5-hour windows, respectively.⁴⁸ As a result of the ECASS III trial, IV t-PA for the treatment of stroke within 3 to 4.5 hours has been supported by the Scientific Advisory from the American Heart Association Stroke Council. The European Medicines Agency has approved the use of IV t-PA within 4.5 hours of symptom onset even though the FDA has not approved it to date.⁴⁹ The third International Stroke Trial evaluated whether t-PA exerted beneficial effects in all patients within 6 hours of symptom onset and in patients older than 80 years. The 18-month follow-up showed no improvement in mortality in those treated with alteplase versus standard care alone (34.9% vs. 35.1%, $P = 0.85$) but did have a modest, statistically significant, improvement in patients with a low (0-2) Oxford handicap scale score (35.0% vs. 31.4%; OR, 1.28; 95% CI, 1.03-1.57; $P = 0.024$).⁵⁰

At present, IV t-PA is the only drug and route of administration approved by the FDA for treating ischemic stroke. However, intraarterial (IA) administration of thrombolytics for treating ischemic stroke is gaining popularity. This method requires a neurointerventionalist to place a catheter into the thrombosed vessel and directly infuse a thrombolytic. Some studies have reported the efficacy of direct IA delivery of thrombolytics. The Prolyse in Acute Cerebral Thromboembolism (PROACT II) study⁵¹ randomized 180 patients with middle cerebral artery occlusion to receive IA prourokinase plus heparin or heparin alone. The results of this study showed that over 40% of patients receiving IA prourokinase plus heparin had improved modified Rankin score of ≤ 2 compared with only 25% patients receiving heparin alone. The MELT trial (a Japanese trial) on IA urokinase was halted early and thus did not reach significance for its primary endpoint.⁵² Nevertheless, secondary analysis of this study and combined analyses with PROACT trials suggested a benefit of IA urokinase.⁵³

Interventional Management of Stroke trialists recently conducted a phase 3 trial to compare a standard dose of IV t-PA with that of IV t-PA bridge for endovascular treatment.⁵⁴ The trial was stopped early due to futility. Patients treated with t-PA and endovascular therapy did not show significant differences compared with those treated with t-PA

TABLE 165-3 Contraindications for Thrombolytic Therapy in Ischemic Stroke

| CONTRAINDICATIONS | RELATIVE CONTRAINDICATIONS |
|---|--|
| Symptom duration of >6 hours | Symptom duration of 3 to 6 hours |
| History of intracranial hemorrhage | Witnessed seizure |
| Evidence of active bleeding | Gastrointestinal or urinary |
| Platelet count of <100,000/mm ³ | Hemorrhage within 3 weeks |
| | Recent lumbar puncture, noncompressible arterial puncture site |
| Prior stroke, head trauma or intracranial surgery within 3 months | Systolic blood pressure of >185 mm Hg or diastolic blood pressure of >110 mm Hg |
| Rapidly improving or only minor symptoms | Mass effect or hypodensity of >½ middle cerebral artery distribution on head computed tomography |
| Major surgery within 14 days | |
| Known arteriovenous malformation or intracranial aneurysm | Glucose level of <50 or >400 mg/dL |
| | Elevated partial thromboplastin time or international normalized ratio (>1.7) |

alone with respect to 90-day mortality (19.1% vs. 21.6%, $P = 0.52$) or modified Rankin score of ≤ 2 (40.8% vs. 38.7%, absolute adjusted difference, 1.5 percentage points; 95% CI, -6.1 to 9.1). The 2013 American Stroke Association guidelines recommend that patients eligible for IV t-PA treatment should receive the treatment even if IA therapy is being considered.⁵⁵ Standard contraindications for IV thrombolytic therapy in patients with acute ischemic stroke are similar to exclusion criteria used in the NINDS study (Table 165-3). Several adjunctive therapies, including mechanical thrombectomy,⁵⁶ glycoprotein IIb/IIIa inhibitors⁵⁷ and ultrasonography,^{58,59} have provided promising results for improving recanalization rates.

Pulmonary Embolism

PE is a major source of morbidity and mortality in hospitalized patients, accounting for up to 15% in-hospital deaths.⁶⁰ Anticoagulation has been the mainstay of treatment for PE since it was first shown to be beneficial in 1960.⁶¹ This has been historically achieved using IV unfractionated heparin (UFH), although subcutaneous (SC) low-molecular-weight heparin (LMWH), SC fondaparinux, or monitored or fixed-dose SC UFH may also be used.⁶² Despite the proven efficacy of anticoagulation for treating acute PE, a significant proportion of patients show incomplete resolution of their occlusion, with subsequent organization of thrombus and obliteration of involved pulmonary artery.⁶³⁻⁶⁵ Therefore, thrombolytic therapy for PE may offer more rapid and complete resolution of thrombus.

The Urokinase Pulmonary Embolism Trial (UPET) was one of the initial trials to evaluate thrombolytic therapy for treating PE.⁶³ This prospective study did not show any improvement in mortality or perfusion rate after 5 days of lytic therapy. However, the UPET and subsequent Urokinase-Streptokinase Embolism Trial showed improvements in small-vessel patency at 2 weeks and 1 year after thrombolytic therapy compared to anticoagulation therapy alone.^{66,67} A 7-year follow-up of this cohort of patients suggested that the risk of pulmonary hypertension decreased after thrombolytic therapy presumably because it resulted in superior clot dissolution.⁶⁸

At present, thrombolytic therapy is used only for treating patients with massive PE resulting in hemodynamic instability. In addition, patients with right ventricular dysfunction or refractory hypoxemia in the setting of preserved systemic arterial blood pressure may benefit from thrombolytic therapy. Right heart strain is correlated with an intermediate risk of death.⁶⁹ Patients with submassive PE showed

TABLE 165-4 Food and Drug Administration–Approved Regimens for Treating Pulmonary Embolism

| DRUG | SYSTEMIC ADMINISTRATION |
|------------------|--|
| Streptokinase | 250,000 U over 30 minutes, followed by 100,000 U/h for 24 hours |
| Urokinase | 4400 U/kg over 10 minutes, followed by 4400 U/kg/h for 12-24 hours |
| t-PA (alteplase) | 100 mg over 2 hours |

improved clinical course after treatment with IV thrombolytic therapy compared to anticoagulation therapy alone; however, IV thrombolytic therapy did not improve long-term mortality.⁷⁰ Pulmonary Embolism Thrombolysis (PEITHO) investigators recently conducted a randomized trial involving 1006 patients with PE, right ventricular dysfunction, and cardiac enzyme elevation to compare TNK-tPA and heparin with placebo and heparin. The primary outcome of death or hemodynamic compromise within 7 days was less frequent in patients in the TNK-tPA group than in those in the control group (2.6% vs. 5.6%; OR, 0.44, 95% CI, 0.23-0.87; $P = 0.02$). Patients receiving thrombolytic therapy showed higher rates of stroke (2.4% vs. 0.2%, $P = 0.003$) and major bleeding (6.3% vs. 1.2%, $P < 0.001$) but similar 30-day mortality (2.4% vs. 3.2%, $P = 0.42$).⁷¹

Verstraete et al. performed the first trial to compare direct pulmonary artery infusion with IV infusion.⁷² However, this trial failed to show a benefit of pulmonary artery infusion. Other adjunctive techniques include use of ultrasound-producing catheters that may increase the permeability of t-PA within a clot. Recently, a prospective, randomized trial comparing the efficacy of ultrasound-assisted catheter-directed thrombolysis (USAT) with that of anticoagulation alone in patients with right heart strain showed the superiority in USAT in reversing the heart strain within the first 24 hours.⁷³ Although no significant differences exist among different thrombolytic regimens,⁷⁴ IV t-PA therapy is preferred because of its short infusion time.⁷⁵ FDA-approved regimens for treating acute PE are listed in Table 165-4. Major hemorrhagic complications occur in approximately 12% of patients irrespective of the lytic agent used.⁷⁶

Deep Venous Thrombosis

The formation of deep venous thrombosis (DVT) is common in acutely ill patients, occurring in as many as 30% of intensive care unit patients despite prophylaxis.⁷⁷ Acute occlusion of the deep venous system leads to severe sequelae such as venous gangrene (phlegmasia cerulea dolens) as well as long-term consequences, including recurrent DVT and post-thrombotic syndrome (PTS).⁷⁸⁻⁸¹ PTS is characterized by persistent pain, edema, discoloration, and ulceration. Patients with ilio-femoral DVT show higher postthrombotic morbidity than those with infrainguinal DVT. Traditional therapy for DVT includes anticoagulation, prevention of thrombus propagation, stabilization of thrombus, and prevention of PE. However, anticoagulation is not effective for restoring and preserving venous function. Thrombolytic therapy of DVT focuses on the dissolution of clot to prevent PTS. The 2014 Cochrane Review, which grouped both systemic and regional thrombolysis with anticoagulation versus anticoagulation alone, found that patients receiving lytic therapy showed more complete clot lysis (RR, 4.91; 95% CI, 1.66-14.53; $P = 0.004$) and lower incidence of PTS (RR, 0.64; 95% CI, 0.52-0.79; $P < 0.0001$). Thrombolysis carried a higher risk of bleeding complications (RR, 2.23; 95% CI, 1.41-3.52; $P = 0.0006$), but there was no significant difference in mortality.⁸²

More recently, catheter-directed thrombolysis (CDT) and pharmacomechanical thrombolysis have evolved as the first-line lytic therapies for DVT because they are theoretically associated with a reduced risk

of bleeding complications. CDT involves catheter-directed infusion of thrombolytic agents that decreases the total number of doses, which in turn decreases systemic side effects. A recent randomized controlled trial (CaVenT study) involving 209 patients showed that patients with first-time iliofemoral DVT who were treated with CDT within 21 days of symptom onset showed improved iliofemoral patency at 6 months (65.9% vs. 47.4%, $P = 0.012$) and reduction in PTS at 2 years (41.1% vs. 55.6%, $P = 0.047$) compared with patients treated with anticoagulation therapy alone. However, patients receiving thrombolytics also developed 20 bleeding complications.¹⁰⁹

The current guidelines put forth by the Society for Vascular Surgery and the American Venous Forum recommend CDT or pharmacomechanical thrombolysis for treating patients with iliofemoral DVT diagnosed within 14 days of symptom onset, good functional capacity, acceptable life expectancy, and low bleeding risk.⁸³ The ACCP also recommended similar guidelines and reported that CDT was a more preferable approach than systemic thrombolysis.⁸⁴ CDT is also recommended for patients with phlegmasia cerulea dolens. In addition to treating patients with lower extremity disease, CDT has been used for treating young patients with primary upper extremity DVT due to effort thrombosis (Paget-Schroetter syndrome) or idiopathic factors.⁸⁵ Results of the Acute Venous Thrombosis: Thrombus Removal With Adjunctive Catheter-Directed Thrombolysis trial will be available in the near future and will help determine the role of thrombolysis for treating DVT.⁸⁶

Acute Peripheral Arterial Occlusion

Acute peripheral arterial occlusion (APAO) is a highly fatal condition that can lead to amputation in 10% to 30% of cases and is associated with a high mortality rate of 15% at 30 days.⁸⁷ Arterial occlusions arise from dissection, trauma, local thrombosis, or emboli. Various noninvasive methods have been developed for treating thromboembolic diseases.

Thrombolysis has become a popular means of treating acute arterial occlusion in certain settings, such as for those without an immediately threatened limb. This approach has been performed since the 1950s.³ Initial attempts involved systemic delivery but were associated with high bleeding risks and poor clinical outcomes. Since the early 1970s, catheter-directed infusion has become the standard of care, which allows higher local thrombolytic concentrations while decreasing the systemic burden of drugs.⁸⁸ Various infusion methods have been developed, including low-dose infusion regimens, high-dose infusion regimens, and high-pressure infusion (pulse spray). However, none of these methods have shown genuine benefit in terms of clinical outcomes.^{89,90}

Although streptokinase was the first agent used for treating APAO, multiple studies have indicated that urokinase and t-PA are more effective for treating APAO than streptokinase, with fewer bleeding complications.⁹¹⁻⁹³ Recently, t-PA and its derivatives have supplanted urokinase as the drugs of choice for treating APAO. The safety and efficacy profiles of low-dose (<2 mg/h, usually beginning at 0.5 mg/h) t-PA regimens are similar to those of urokinase with adjunctive heparin infusion to maintain the aPTT at 1.5 times of that at baseline. With this regimen, over 60% of patients have shown complete resolution and 30% of patients have shown partial resolution of thrombus within 24 hours of treatment initiation.⁹⁴ An advisory panel on CDT recommended weight-based dosage (0.001 to 0.02 mg/kg/h) or non-weight-based dosage (0.12 to 2.0 mg/h), with total doses not exceeding 40 mg.⁹⁵

Use of thrombolytics for treating APAO is part of a multifaceted approach that often involves additional endovascular techniques and/or surgical interventions. The Rochester trial compared initial surgery with urokinase treatment in 114 patients with severely threatened limbs.⁹⁶ Limb salvage rates in the two groups were identical (82%) at 12 months; however, mortality was significantly lower in patients treated with urokinase (16% vs. 42%). The Surgery or Thrombolysis for the Ischemic Lower Extremity trial examined 393 patients randomized

to undergo surgery or one of two lytic therapies (rt-PA or urokinase).⁹⁷ At 30 days, limb loss rates (5% with lysis vs. 6% with surgery) and mortality rates (4% vs. 5%, respectively) were similar between the two groups. Subgroup analyses^{98,99} performed in this study showed higher benefit of thrombolytic therapy in patients with graft occlusion than in those with native vessel occlusion and acute ischemia of less than 2 weeks. The TOPAS trial compared recombinant urokinase therapy with surgery in 544 patients.^{100,101} Although it failed to demonstrate an amputation-free survival benefit at 1 year (68% for urokinase, 69% for surgery), it did show that over 30% of the patients treated with urokinase were not only alive without amputation but also had nothing more than a percutaneous procedure at 6 months. Thus, a significant number of patients can avoid surgery after using thrombolytic therapy. A contemporary series by Taha et al. comparing the effectiveness of endovascular (154 limbs) versus surgical (326 limbs) revascularization for acute limb ischemia also showed similar amputation rates at 1 year (13.0% vs. 19.6%, $P = 0.074$). In this study, 1-year mortality was significantly lower in patients in the endovascular group (12.9% vs. 33.8%, $P < 0.001$).¹⁰²

A 2013 Cochrane Review identified five prospective, randomized trials from the 1990s that compared surgery with thrombolytic therapy for managing acute limb ischemia. The review did not show any overall difference in limb salvage or mortality at 1 year. As expected, patients treated with thrombolytic therapy showed a higher rate of stroke (1.3% vs. 0%) and major hemorrhage (8.8% vs. 3.3%).¹⁰³ Therefore, thrombolytic therapy is still not considered as the standard of care for treating APAO. However, it may be useful for treating patients who are poor candidates for surgery. In some cases, thrombolysis can aid in recanalization of distal vessels that are not patent at treatment initiation, thus permitting subsequent revascularization through bypass surgery. Moreover, it may be the best approach for treating patients with occluded bypass grafts^{97,98} (Fig. 165-4). Use of lytic agents is contraindicated in patients with early postoperative thrombosis, thrombosis after penetrating or multiple trauma, or irreversible ischemia in the limbs.

Other Applications

In addition to the previously listed indications for thrombolytic therapy, another common application is the treatment of thrombosed dialysis grafts or central venous catheters. Although the ultimate goal is to recognize and treat a graft before its failure, thrombolytic treatment can play an important role if the graft is occluded. Several techniques have been used for treating acutely thrombosed grafts, including mechanical thrombectomy, surgical revision, and pharmacologic thrombolysis. A recent meta-analysis indicated that surgical thrombectomy remains the standard of care and is associated with superior patency¹⁰⁴ presumably because of anastomotic revision, which is performed concurrently. In patients with occluded central venous catheters, a 2-mg (1 mg/mL) aliquot of alteplase may be used for treating each occluded lumen for up to 2 hours.⁹⁵ Multiple studies have shown this regimen to be both safe ($\leq 1\%$ bleeding risk) and efficacious ($\approx 90\%$ patency after two treatments).¹⁰⁴⁻¹⁰⁶

MANAGEMENT/LABORATORY VALUES

Administration of thrombolytic agents decreases the levels of circulating plasminogen and fibrinogen. Fibrinogen is degraded during fibrinolysis, reaching nadir values between 5 and 7 hours after therapy initiation.¹⁰⁷ In most patients, these values return to baseline within 48 hours after lysis. Fibrin degradation products are a reliable indicator of fibrinolytic activity because degradation of fibrinogen or fibrin by plasmin is the only source of these products in humans.

Monitoring of fibrinogen levels every 6 to 8 hours is recommended during lytic therapy, with a decrease in dose or discontinuation of infusion if levels decrease to below 100 mg/dL. In addition, platelet counts should be monitored daily or every alternate day. Thrombocytopenia occurs in as many as 10% patients receiving rt-PA compared

FIGURE 165-4 ■ Successive angiograms showing occluded popliteal artery (arrow, **A**) treated with thrombolytics. After thrombolysis, a focal popliteal artery stenosis is observed (arrow, **B**) along with patent distal vessels. This area was subsequently treated by performing balloon angioplasty (**C**). Thrombolysis and angioplasty resulted in a patent popliteal artery (arrow, **D**), with good distal arterial flow.

with less than 1% patients receiving streptokinase.¹⁰⁸⁻¹¹⁰ If bleeding occurs, thrombolysis should be discontinued and blood products—namely, fresh frozen plasma or cryoprecipitate—should be administered as appropriate to correct the patient's coagulopathic state.

CONCLUSION

Although evidences strongly support the use of thrombolytic agents for treating various occlusive vascular disorders, this treatment is

administered in relatively few patients. Increasing data support the safety and efficacy of thrombolytic therapy, which has substantially increased its use over the past decade. One of the challenges in the coming years will be to more clearly define patients who will benefit the most in terms of both decreased mortality and prevention of hemorrhagic complications. Evolution of technology, including diagnostic modalities, mechanical clot busters and adjuvant therapies, will expand the indications for thrombolytic therapy.

KEY POINTS

1. Thrombolytics comprise a diverse group of compounds that convert plasminogen to plasmin.
2. Thrombolytic therapy is indicated within 6 hours of the onset of acute myocardial infarction, especially in patients who are not eligible for primary angioplasty.
3. Patients with acute ischemic stroke receive the highest long-term benefit from thrombolytic therapy when performed within 4.5 hours of symptom onset.
4. The role of thrombolytic therapy in pulmonary embolism is controversial and limited largely to patients with hemodynamic instability.
5. Urokinase and tissue plasminogen activator are commonly used for managing acute peripheral occlusion. Highest benefit is observed in patients with occlusions for less than 14 days and in those with previous extremity bypasses.
6. Thrombolytic therapy requires intensive monitoring and follow-up radiography. Fibrinogen levels should be monitored every 6 to 8 hours, and patients should be closely monitored for signs of major hemorrhage.

Atherosclerosis and its thromboembolic complications are leading causes of mortality and morbidity. This progressive disorder usually remains clinically silent until it causes end-organ damage resulting in stroke, ischemic heart disease, and peripheral vascular insufficiency. Atherosclerosis characteristically affects the aorta, with the abdominal aorta more widely involved than the thoracic aorta. Lower limb vessels are more frequently affected than upper limb vessels, while renal, pulmonary, and mesenteric vessels are the least susceptible.

Nearly half of all strokes were thought to result from cerebral vasospasm until the 1950s, when Fisher stressed the etiologic importance of emboli from carotid artery atherosclerotic plaques.¹ Although embolization from the heart and major vessels accounts for a large number of ischemic cerebrovascular accidents, the cause of a significant proportion remains undetermined² and is thought to be embolic in origin. The following account will focus on the pathophysiology, clinical consequences, detection, prevention, and management of atheromatous embolization.

■ PATHOPHYSIOLOGY

Atherosclerosis

The process of atherosclerosis may begin as early as childhood, developing slowly with effects rarely manifesting before the fourth or fifth decades of life. Traditional risk factors include hypertension, diabetes, smoking, and hypercholesterolemia.

Atherosclerosis mainly affects large and medium-sized arteries. Intravascular sites of blood turbulence favor the development of atherosclerotic lesions. Initial changes in arterial wall morphology result in the formation of fatty streaks that consist of lipid-engorged macrophages in the arterial intima. Progression of such precursor lesions occurs secondary to an inflammatory process initiated by endothelial injury and dysfunction.³ Insufficient nitric oxide production results in increased adhesion and aggregation of platelets. Upregulation of the expression of endothelial adhesion molecules and selectins leads to the accumulation of monocytes and T lymphocytes. These cells become activated and produce growth factors, cytokines, and chemokines. Smooth muscle cells migrate from the media into the intima and proliferate. In time, these lesions develop into raised, fibrous plaques consisting of a fibrous cap covering a core containing necrotic material, lipids, and cholesteryl esters. This advanced plaque forms the base onto which the complex plaque develops, consisting of fissures, erosions, or ulceration. Interest has increased in the role of monocytes and macrophages in the pathogenesis of plaque progression and rupture,⁴ processes that are related to thrombosis, embolism, and clinical manifestations.

Atheromatous Embolization

Atheromatous embolization is a descriptive term for embolization of any atheromatous material. *Atheroembolization* refers to the dislodgment of vascular plaque material that contains cholesterol crystals, red blood cells, and fibrin.⁵ This “cholesterol emboli” syndrome comprises renal failure, skin lesions, blue toes, and neurologic manifestations. It can develop spontaneously (due to plaque rupture) or following the use of thrombolytics or anticoagulants⁶ or result from arterial

manipulation (during surgical procedures, cardiac catheterization, or insertion of an intraaortic balloon pump [IABP]).⁷ Disruption of a vascular plaque results in the release of cholesterol crystals with subsequent downstream vascular obstruction and initiation of an inflammatory process with lymphocytic and mononuclear cell infiltration. Biopsy specimens of affected organs such as skin or kidneys are usually diagnostic.

Plaque Morphology and Embolic Risk

Severe atherosclerosis of the ascending aorta appears to be the most important morphologic indicator of an increased risk of atheromatous embolization. The French Aortic Plaque in Stroke group identified a plaque thickness of 4 mm or greater on transesophageal echocardiogram (TEE) as an independent predictor of recurrent embolization.^{8,9} Plaque ulceration and morphology may contribute to an increased risk of embolic events, with evidence of pedunculated, mobile plaques and the absence of calcium conferring a higher risk.^{10,11} The cerebral embolic risk is also influenced by plaque location; as complex plaques are more frequent distal to the ascending aorta, there is increased risk to the left cerebral hemisphere and the peripheral circulation.¹⁰

Macroembolization and Microembolization

Emboli can be divided into macroemboli and microemboli, also described as thromboembolism and atheroembolism. Despite sharing the same underlying pathophysiology, clinical manifestations differ. Thromboemboli affect arteries larger than 200 μ m in diameter, while atheroemboli affect smaller arteries, arterioles, and capillaries.¹² Macroemboli may cause overt clinical presentations (e.g., stroke or peripheral ischemia) while microemboli tend to be more occult in their manifestations of end-organ injury or dysfunction (e.g., renal injury, neuropsychological impairment). Embolization may arise spontaneously or be related to vascular interventions and cardiovascular surgery. The complex aortic-plaque-related 3-year mortality is reported to be as high as 20%.¹³

■ CLINICAL CONSEQUENCES OF ATHEROMATOUS EMBOLIZATION

Cerebral

As the prevalence of aortic atherosclerotic disease increases with age, so does the rate of atheromatous embolization. Postmortem studies indicate that it affects 20% of patients in their fifth decade, increasing to 80% in those in their eighth decade.¹⁴ Emboli from the atherosclerotic thoracic aorta commonly result in stroke (50%) and transient ischemic attack (35%),¹³ with the middle cerebral artery being the most frequent site of arterial embolism. Stroke has profound effects; outcomes from acute stroke are measured in terms of survival, functional independence, and financial cost. Survival after stroke is significantly poorer than after myocardial infarction (MI) or most cancers and is the leading cause of disability in developed countries.¹⁵

Cholesterol emboli (atheroembolization) are an important and frequently unrecognized cause of stroke.¹⁶ Microembolization is a recognized cause of more subtle, sometimes subclinical neurologic injury.^{17,18} This injury is manifested by subtle changes in cognitive function that

may only be evident on detailed neuropsychological testing^{19,20} and include amaurosis fugax, transient ischemic attack, and confusional state. Rarely, embolization to the spinal cord can lead to lower extremity paralysis. The importance of microembolization has increased over recent years, particularly in patients undergoing cardiac surgery.²¹

Cardiac

Atherosclerotic disease is the leading cause of death in developed countries. Every year it results in over 19 million deaths worldwide, and coronary heart disease accounts for the majority of those.²² Most acute coronary syndromes are due to plaque rupture. Distal embolization of cholesterol and atheromatous material may be important in the pathogenesis of some acute coronary syndromes.²³ The occurrence of distal coronary embolization in the setting of acute coronary syndromes has been followed using serum levels of cardiac troponins to detect small degrees of myocardial necrosis. Embolization following percutaneous coronary interventions is well recognized, and elevated troponins are seen in up to 44% of patients.^{24,25}

Peripheral

Peripheral emboli most frequently lodge in the lower extremities. Cholesterol atheroembolization may be subclinical or result in systemic effects. While renal, neurologic, and cutaneous manifestations tend to dominate the clinical picture, involvement of most organs has been reported.

Cholesterol embolization frequently manifests as acute kidney injury^{26,27} and can even lead to renal failure.^{26,27} In those cases, renal biopsy is diagnostic.²⁸ Cutaneous manifestations, including livedo reticularis and the “blue-toe” syndrome, are the most common signs of atheroembolism, occurring in up to 34% of cases.²⁹ Atheroemboli from the carotid vessels give rise to retinal emboli,³⁰ resulting in visual symptoms. The mesenteric circulation may also be affected, resulting in small bowel bleeding³¹ and intestinal infarction. The pancreas, liver, and gallbladder may also be involved.³² More rarely, involvement of transplanted viscera such as the kidney may result in renal failure.³³

■ DIAGNOSIS AND SCREENING

Full clinical assessment and screening of patients presenting with embolic complications are essential in guiding management and prevention strategies. Diagnosis of cholesterol embolization syndrome relies on clinical findings in patients with atherosclerotic disease and a history of recent vascular intervention. As different organs can be involved, a high index of clinical suspicion is vital. It is important to differentiate between atheroembolism and thromboembolism, as the treatment may be guided accordingly.

Many imaging modalities have been used to visualize atherosclerotic plaques; some in routine clinical practice and others reserved for research. Technological advances in imaging have provided tools that allow primary prevention by identifying those at highest risk, enabling appropriate disease-modifying treatment to be initiated.

X-Ray Angiography

X-ray angiography is an invasive procedure that allows assessment of the vascular lumen. However, it is not as sensitive in plaque detection as other imaging modalities and also confers an additional risk of plaque disruption secondary to instrumentation. Despite these limitations, angiography is still regarded as the gold standard for imaging coronary, carotid, and peripheral arterial disease.³⁴

Surface and Transesophageal Ultrasonography

Measurement of carotid and aortic wall thickness as well as qualitative and quantitative assessment of atherosclerotic plaques can be determined using ultrasonography. The North American Symptomatic

Carotid Endarterectomy Trial and the Asymptomatic Carotid Artery Stenosis Study have shown that the degree of stenosis and its hemodynamic consequences are important in the development of stroke.^{35,36} High-resolution, real-time B-mode ultrasound with Doppler flow imaging is currently considered the modality of choice in imaging the carotid arteries.³⁷

With respect to screening, carotid intima-medial thickness (CIMT) measured by B-mode ultrasound is assessed as a risk factor and a marker for vascular disease risk. This marker most accurately represents subclinical vascular disease but not plaque formation or atherosclerosis per se. Epidemiologic and clinical trial evidence, digitization, and standardization have made CIMT a validated and accepted marker for generalized atherosclerosis burden and vascular disease risk.³⁸ CIMT is a predictor of coronary events and stroke, as well as all-cause mortality.^{39,40} The American Society of Echocardiography Carotid Intima-Media Thickness Task Force recommends the use of CIMT measurement by ultrasound in intermediate-risk asymptomatic patients, with a goal of predicting future coronary heart disease events.⁴¹

Transesophageal echocardiography (TEE) is a quick and safe procedure with widespread use ranging from the operating theatre to the bedside.⁴² TEE is the procedure of choice for the detection, assessment, and characterization of thoracic aortic atherosclerosis. TEE can reliably detect intimal thickening, ulceration, calcification, and the presence of mobile components within the aortic plaque (Fig. 166-1). The French Aortic Plaque in Stroke investigators used TEE to assess aortic plaque thickness in patients with stroke, reporting that increased plaque thickness imparted a significant increase in stroke risk.^{8,9} Katz and colleagues used the following 5-grade ranking system to indicate the severity of aortic atherosclerosis as assessed using TEE in 130 patients undergoing cardiac surgery with cardiopulmonary bypass: grade 1, normal aorta; grade 2, flat intimal thickening; grade 3, protruding atheroma in the aortic lumen (<5 mm); grade 4, protruding atheroma (>5 mm); and grade 5, atheroma with a mobile thrombus.⁴³ Patients with grade 5 lesions were at highest risk of stroke. Logistic regression identified aortic arch atheroma as the only variable that was predictive of stroke, with an odds ratio of 5.8. Another study of 315 coronary artery bypass graft (CABG) patients undergoing intraoperative TEE also reported a significant increase in the risk of stroke in patients with aortic arch intimal thickening of greater than 5 mm.⁴⁴

It is no surprise that patients with the highest risk carotid lesions also have high-risk aortic plaques. Assessment of the carotid arteries as well as the aorta is prudent in the investigation of atherosclerotic patients who have suffered embolic events.

Intraoperative Epi-aortic Ultrasound

Epi-aortic ultrasonography involves intraoperative imaging of the ascending aorta using a sterile-sheathed transducer. This technique is

FIGURE 166-1 ■ Transesophageal echocardiogram image showing an aortic plaque measuring 57 mm.

noninvasive and has been used in the context of cardiac surgery to detect areas of ascending aortic atherosclerosis,⁴⁵ thus allowing modification of the surgical technique in an attempt to reduce potential embolic complications.⁴⁶ The main disadvantage of this technique is suboptimal imaging of the aortic arch. Intraoperative epi-aortic ultrasound can therefore be used to complement the information on the aortic arch obtained by TEE.

Transcranial Doppler

Transcranial Doppler (TCD) ultrasonography can be used to detect and quantify cerebral microemboli. Ultrasound probes are placed bilaterally on the temple, overlying the middle cerebral vessels. Emboli cause an increase in the reflected ultrasound, causing high-intensity transient signals (HITS). These HITS are the footprints of microemboli, which may consist of air, fat, atheromatous material, or platelet-fibrin emboli. In addition to detecting cerebral microemboli, TCD can be reliably used to assess cerebral vasomotor reactivity and autoregulation, to document the circle of Willis functional status, and to identify cerebral hypo- and hyperperfusion, recanalization, and reocclusion.⁴⁷

TCD can reliably detect HITS intraoperatively and has been used extensively in the context of cardiac and carotid surgery. During cardiac surgery, microemboli can be detected following intraoperative aortic manipulation (aortic cannulation and application and removal of aortic cross-clamp) as well as during cardiopulmonary bypass.⁴⁸ HITS have also been identified in patients with symptomatic carotid artery stenosis,⁴⁹ patients with prosthetic heart valves,⁵⁰ and those with aortic atherosclerosis.⁵¹ Their presence is a significant independent predictor of early recurrence of stroke.⁵²

A major limitation is an inadequate acoustic window in 5% to 20% of individuals.⁵³ With multirange, multifrequency Doppler systems, automatic artifact rejection and differentiation between solid and gaseous microemboli have become possible with high sensitivity and specificity.^{54,55} A significant reduction in intraoperative cerebral microembolism as well as a reduction in the proportion of solid microemboli has been reported with TCD, with avoidance of cardiopulmonary bypass and minimizing manipulation of the ascending aorta during cardiac surgery.^{48,56}

An exciting recent development with TCD ultrasonography is its therapeutic use in the treatment of stroke. This procedure involves the use of TCD ultrasound to augment the effect of fibrinolysis and has been shown to at least double the chance of early complete arterial recanalization.⁵⁷

Computed Tomography

Computed tomography (CT) can be used for imaging the aorta and quantifying aortic wall calcification. Contrast-enhanced CT has been proposed as a valuable method for following the progression and regression of atherosclerotic disease.⁵⁸ The main advantage over TEE is the ability to completely image the thoracic and abdominal aorta. Disadvantages include radiation and contrast exposure with potential for renal damage, limiting its use in asymptomatic populations.

Coronary multidetector CT angiography (MDCTA) can be used in identifying patients at a particularly high risk of dying suddenly or suffering a nonfatal MI. It provides information on coronary artery stenosis as well as an estimate of calcification, coronary artery calcium (CAC). The latter is related to multiple risk factors of coronary artery disease. The importance of CAC screening lies in its potential to increase the predictive power of testing for future events.^{40,59}

Magnetic Resonance Imaging Techniques

Magnetic resonance imaging (MRI) has emerged as a leading noninvasive imaging modality for atherosclerotic disease. MRI can be used to image atherosclerotic plaques in aortic, carotid, peripheral, and coronary arterial disease.^{60,61} Its major strengths rest in its ability to

determine plaque morphology. Using a range of techniques, MRI can provide valuable information on the composition of the atherosclerotic plaque by identifying the three main factors that determine plaque stability: (1) presence of a lipid core, (2) thickness of the fibrous cap, and (3) inflammation within the cap. MRI allows identification of high-risk unstable plaques and thus guides intervention and therapy⁶² as well as monitoring response to therapy with statins.⁶³ Magnetic resonance angiography has a high sensitivity and specificity and can be used to image the aorta, carotid, renal, and other peripheral vessels. Evolving magnetic resonance techniques include intravascular⁶⁴ and transesophageal⁶⁵ MRI.

Tissue Diagnosis

Cholesterol embolization can only be confirmed with biopsy, as the clinical manifestations are often subtle and nonspecific compared to those of thromboembolism. Cholesterol clefts in arterioles are evidence of cholesterol crystal emboli that have dissolved during the process of fixation of the specimen. Intimal proliferation of the arterial vascular bed following cholesterol crystal embolization may be responsible for the end-organ malperfusion.⁶⁶

VASCULAR MANIPULATION AND EMBOLIC EVENTS

Cardiac Surgery

Stroke, transient ischemic attack, and peripheral embolization are potential complications following cardiac surgery. Atheroembolism results in a variety of clinical manifestations and can be fatal in about 20% of patients.⁶⁷ Stroke affects less than 2% of CABG patients and is higher in those undergoing open-heart procedures.⁶⁸ The risk of perioperative stroke increases with advancing age, and those with concomitant cardiovascular risk factors are at highest risk.⁶⁹ Additionally, female sex is independently associated with a significantly higher risk of perioperative stroke.⁷⁰ Embolization from the atheromatous aorta is the single most important etiologic factor for stroke. This risk arises during intraoperative manipulation of the aorta, including cannulation for cardiopulmonary bypass, application, and removal of aortic cross-clamp for administration of cardioplegia, and the use of side-clamps for anastomosis of the proximal end of the graft to the aorta.⁷¹ Patients undergoing cardiac surgery with aortic plaque greater than or equal to 5 mm had a higher incidence of stroke.⁷² As previously mentioned, mobile plaques confer a greater risk of stroke. This effect was seen in an analysis of 130 patients undergoing coronary artery bypass grafting, with a higher incidence of stroke in the cohort in whom mobile plaques were identified.⁷³ Roach et al. showed that atherosclerosis of the ascending aorta is the strongest independent predictor of perioperative stroke, with an odds ratio of 4.5.⁷⁴

Cardiac Catheterization and Peripheral Vascular Intervention

Aortic manipulation during cardiac catheterization procedures or intraaortic balloon pump (IABP) insertion may cause embolization from aortic atheroma. In a report comparing 59 patients with atherosclerotic aortic debris undergoing transfemoral cardiac catheterization, an embolic event occurred in 17% of the patients with atherosclerotic aortas compared to 3% of controls.⁷⁵ In the proportion of patients requiring IABP, 5 out of 10 patients with atherosclerotic aortas had an embolic event compared with none of the 12 patients with IABP in the control group. When a transbrachial approach was used in patients with atherosclerotic aortas, none of 11 patients suffered an embolic event. Patients with mobile aortic atheromas on TEE are at highest risk of catheter-related embolization.⁷⁵ A recent study reported the rate of clinically significant distal embolization in 2.4% of patients undergoing peripheral arterial intervention.⁷⁶

Cholesterol embolization can complicate cardiac catheterization. Because it is commonly asymptomatic, the exact incidence is uncertain and mainly depends on the detection criteria used (clinical or pathologic). Cholesterol can be identified in the lumen of affected arterioles in up to 12% of patients following cardiac catheterization.⁷⁷ A prospective multicenter study reported cholesterol embolization in 1.4% of patients following cardiac catheterization based on evidence of peripheral cutaneous involvement or renal dysfunction.⁷⁸ The syndrome occurred more frequently in patients with generalized atherosclerosis.

PREVENTION AND MANAGEMENT

Treatment of atheromatous embolization depends on the clinical manifestation. However, evidence of atherosclerotic disease with plaque should be considered a cardiovascular risk factor, and preventive measures should be taken despite the symptomatic status of the individual. General measures include identification and modification of risk factors. Patients with the clinical syndrome of cholesterol embolization have a generally poor prognosis, particularly when there is evidence of visceral and renal involvement. Supportive management with blood pressure control and, if necessary, renal replacement therapy is indicated. Strategies for the general prevention and management of atheromatous embolization are discussed here.

Antiplatelet Agents and Anticoagulants

As thrombi can develop on and embolize from atherosclerotic plaques, it seems logical to use antiplatelet agents or anticoagulants to prevent these thromboembolic complications. Three studies have reported a reduction in the risk of stroke with anticoagulation.⁷⁹⁻⁸¹ These studies, however, were not randomized and did not include long-term follow-up. A randomized trial reported that in patients with stroke, large aortic plaques remain associated with an increased risk of recurrent stroke and death at 2 years despite treatment with warfarin or aspirin.⁸²

The ARCH (Aortic Arch Related Cerebral Hazard) trial was an open-label trial where patients with aortic arch atheroma (4 mm or greater) and nondisabling stroke were assigned to warfarin (target INR, 2.0-3.0) versus aspirin (75 mg/d) plus clopidogrel (75 mg/d) and followed longitudinally to determine which treatment was superior for secondary stroke prevention. Unfortunately, the trial was stopped prematurely and was underpowered to determine a difference in the primary end points of cerebral infarction, myocardial infarction, peripheral embolism, and intracranial hemorrhage, although vascular death was significantly lower in the dual antiplatelet cohort.⁸³ The main concern with anticoagulation is the risk of plaque hemorrhage and atheroembolization.⁸⁴ However, the risk of clinical atheroemboli syndrome during warfarin therapy in such patients appears to be low (only 1 episode in 134 patients according to the Stroke Prevention in Atrial Fibrillation trial).⁷⁹

In patients with atherosclerosis, acute ischemic events are usually precipitated by thrombosis, and antiplatelet agents play a fundamental role in thrombosis prevention. Routine use of aspirin in high-risk patients is universally recommended.⁸⁵ The Antithrombotic Trialists' Collaboration published a major meta-analysis with over 200,000 patients, assessing the effect of antiplatelet therapy in patients with various manifestations of atherosclerosis. This study reported a significant reduction in the rate of stroke, MI, or vascular death in those on antiplatelet therapy.⁸⁶

Aspirin is the most commonly used antiplatelet agent. It inhibits thromboxane-dependent platelet aggregation. Thienopyridines, including clopidogrel and ticlopidine, act by blocking adenosine diphosphate (ADP)-dependent activation of platelets. There is evidence that thienopyridine derivatives are modestly but significantly more effective than aspirin in preventing serious vascular events in patients at high risk, but there is uncertainty about the size of the additional benefit.⁸⁶ The thienopyridines are also associated with less

gastrointestinal hemorrhage and upper gastrointestinal upset compared to aspirin but with an excess of rash and diarrhea.⁸⁷ In the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial, a long-term benefit was observed with the use of clopidogrel in addition to aspirin in high-risk patients (unstable angina and non-Q-wave MI).⁸⁸

Platelet activation leads to a conformational change in glycoprotein IIb/IIIa, the major fibrinogen receptor on platelets. Intravenous glycoprotein IIb/IIIa inhibitors (e.g., abciximab) are generally reserved for the high-risk setting of percutaneous coronary intervention.

Dextran has antiplatelet and intravascular volume expansion effects. Postoperative or perioperative administration of 10% dextran 40 reduces the rate of TCD-detected microembolic signals after carotid endarterectomy.^{89,90} Dextran, however, may interfere with cross-matching blood and cause bleeding, renal failure, or (occasionally) acute allergic reactions.

The Guidelines for the Diagnosis and Management of Patients with Thoracic Aortic Disease have been published by the ACCF/AHA. Oral anticoagulation therapy with warfarin (INR, 2.0-3.0) or antiplatelet therapy in stroke patients with aortic arch atheroma 4.0 mm or greater to prevent recurrent stroke was a class IIb recommendation (level of evidence, C).⁹¹ However, ACCP guidelines from 2012 recommend that patients with aortic disease with no previous neurologic event have no indication for anticoagulation.⁹²

Statins

There is a clear association between elevated levels of plasma cholesterol and atherosclerotic disease. Statins or 3-hydroxy-3-methylglutaryl coenzyme-A (HMG Co-A) reductase inhibitors reduce the hepatocyte cholesterol content and increase expression of LDL-cholesterol receptors, resulting in a drop in serum low-density lipoprotein (LDL) cholesterol. In addition, it has become evident in recent years that statins possess cholesterol-independent or pleiotropic effects. These include improvement of endothelial function by improving the bioavailability of nitric oxide, decreasing vascular inflammation, and stabilizing plaques.⁹³ Statins are widely used in primary and secondary prevention of ischemic heart disease. A meta-analysis of randomized placebo-controlled double-blind trials with statins reported a 30% reduction in stroke risk with statin therapy.⁹⁴ Another meta-analysis of data pooled from over 49,000 patients treated with statins in 28 trials reported a relative risk of stroke of 0.76 in statin-treated patients.⁹⁵ Tunick et al. showed that statin therapy was independently and significantly protective against the occurrence of embolic events (risk ratio, 0.39) in patients with severe thoracic aortic plaque.¹³

Plaque size reduction, stabilization, and prevention of plaque thrombosis may be the mechanisms leading to a reduction in atheromatous embolization. Two randomized studies of low-dose and higher dose statins in patients with aortic and/or carotid plaques showed significant regression in plaques seen on MRI.^{96,97}

Minimal Aortic Manipulation

The use of smaller arterial catheters during cardiac catheterization may help reduce the risk of embolization.⁹⁸ Reduction of embolization during cardiac surgery is possible with modifications to the operative technique. Avoidance of aortic manipulation intraoperatively is most important.⁷¹ This can be achieved in patients undergoing CABG by avoidance of cardiopulmonary bypass, which obviates the need for aortic cannulation and cross-clamping.^{99,100} The use of composite arterial grafts (bilateral internal thoracic artery grafts with the radial artery anastomosed to the internal thoracic artery) avoids the need for proximal aortic anastomosis requiring a side-clamp.¹⁰¹ Off-pump surgery has been shown to offer a reduction in the risk of stroke in patients with atheromatous aortas.¹⁰² We have reported a significant reduction in cerebral microembolization by avoiding cardiopulmonary bypass and aortic manipulation.^{48,56} A strategy for potential prevention of embolization in cardiac surgery is summarized in [Box 166-1](#).

BOX 166-1

Prevention of Embolization During Cardiac Surgery in Patients with Atherosclerosis

- Establish the patient's preoperative risk factors.
- Image the ascending aorta and arch preoperatively.
- Assess the carotid arteries.
- Assess the ascending aorta using intraoperative epiaortic ultrasound.
- Use evidence-based decisions to reflect the operative technique.
- Decide the site and risk of cannulation.
- Avoid repeated aortic clamping.
- Consider no-touch aortic techniques.
- Perform off-pump surgery with composite arterial grafting where possible.

Surgical Treatment

Treatment of patients with symptomatic carotid atherosclerosis is well established. The European Carotid Surgery Trial (ECST) and North American Symptomatic Carotid Endarterectomy Trial (NASCET) investigators reported a clear benefit of carotid endarterectomy in the prevention of stroke in patients with high-grade, recently symptomatic carotid stenosis.^{35,103} This benefit is offset by the surgical risk of the procedure. The perioperative stroke and death rate for patients with high-grade stenosis was 8% at 30 days in ECST and 6% in NASCET. These rates are acceptable, given the absolute risk reduction by surgery of 10% and 17%, respectively. However, for patients with asymptomatic carotid disease, the risk-to-benefit ratio is narrower, and carotid endarterectomy is currently only recommended for high-grade carotid stenosis (70%-99%).

The international carotid stenting study looked at angioplasty and stenting of the carotid vessels as an alternative to endarterectomy. However, they reported higher rates of stroke and mortality with carotid stenting compared to endarterectomy and therefore recommended that carotid endarterectomy should remain the treatment of choice.¹⁰⁴

Management of patients with recurrent embolic events due to aortic atherosclerotic disease can be problematic. Aortic arch endarterectomy in patients with severe aortic atherosclerosis has been reported.¹⁰⁵⁻¹⁰⁷ This procedure is performed using deep hypothermic circulatory arrest and is associated with significant perioperative morbidity and

mortality. When performed during cardiac surgical procedures using cardiopulmonary bypass, it resulted in a significantly higher rate of stroke and mortality. Therefore, there is insufficient evidence to recommend this mode of treatment for stroke prevention. In the context of cardiac surgery, replacement of the ascending aorta can be performed with acceptable mortality and morbidity,¹⁰⁸ particularly in the intraoperative management of patients with so-called porcelain aorta¹⁰⁹ (severe diffuse atherosclerosis and calcification of the ascending aorta that causes an eggshell appearance on x-ray or CT).

With increasing interest in endovascular surgery, stenting as a means of preventing subsequent embolization from aortic plaque has been explored with some success. This involves the use of covered stents to exclude the plaque disease. This minimally invasive approach may offer a treatment strategy for patients who are unfit for conventional surgery despite its inherent risk of embolization secondary to instrumentation.^{110,111}

KEY POINTS

1. Atherosclerosis and its thromboembolic complications are a leading cause of death in the Western world.
2. The risk of atheromatous embolization increases significantly with increasing plaque thickness (>4 mm) and the presence of ulceration.
3. Ultrasonography (transesophageal and surface) is one of the most frequently used investigative techniques. Computed tomography provides information on coronary artery atherosclerosis and the degree of calcification. Magnetic resonance imaging provides very high resolution in imaging plaque morphology.
4. The risk of embolization increases significantly during cardiac surgery and vascular interventions.
5. The use of antiplatelet agents and statins is recommended in all patients with significant atherosclerotic disease.
6. Perioperative aortic screening allied with minimal aortic manipulation during cardiac surgery in high-risk patients may be associated with a significant reduction in the rate of atheromatous embolization.

ANNOTATED REFERENCES

■ EPIDEMIOLOGY

A *pressure ulcer* is any wound that develops in the upper and outer layers of the skin because of sustained external pressure.¹ Pressure ulcers are serious complications in hospitalized patients. They increase health care costs, decrease patients' quality of life, and often result in prolonged hospital stay. Current estimates of the prevalence of pressure ulcers in hospital patients vary between 5% and 17%. In the largest investigation to date, the incidence of hospital-acquired pressure ulcers was 4.5%, and the prevalence of pressure ulcers on admission was 5.8%. More significantly, almost 1 in 5 patients admitted with a previously acquired pressure ulcer developed an additional pressure ulcer at a different site during their hospital stay.^{2,3} The prevalence of pressure ulcers is higher (up to 30%) among residents of long-term geriatric facilities, whereas the majority of pressure ulcers (50%) in hospitalized patients are stage I ulcers, and the prevalence of stage III and IV ulcers is estimated to be as high as 4% in patients residing in long-term care facilities.

■ RISK FACTORS

Multiple risk factors associated with the development of pressure ulcers are listed in [Tables 167-1](#) and [167-2](#).³ These factors can be categorized as intrinsic, which are related to a patient's preexisting medical condition(s), and extrinsic factors, which are related to a patient's environment. Intrinsic risk factors include neurologic disease, motor impairment, cognitive impairment, sensory deficits, malnutrition, and hypoperfusion due to peripheral vascular disease or congestive heart failure. Extrinsic risk factors include inadequate mobilization by care providers, trauma, sedation, application of physical restraints, improper positioning (especially among patients under general anesthesia), moisture, and shearing forces. Of these risk factors, failure to frequently change position is thought to be the biggest contributor to pressure ulcer formation. A combination of improper positioning and moisture on the skin surface is a frequent cause of pressure ulcer formation in critically ill patients.

Because of the underlying pathophysiology of pressure ulcer formation, there are several high-risk areas for the development of pressure ulcers. Pressure ulcers are more prone to develop in bony or cartilaginous areas. These include any area of the body with limited soft tissue coverage, such as the coccyx, spinous processes, heels, elbows, and ankles. In patients who are mostly positioned on their side, the iliac crest and trochanters are considered high-risk areas. Additionally, patients with malnutrition and subsequent cachexia have significant loss of soft tissue and are more prone to the development of pressure ulcers at any location.

■ PATHOPHYSIOLOGY

Pressure ulcers develop because of hypoperfusion to an area. The principle underlying pressure ulcer development is simple. When externally applied pressure exceeds capillary perfusion pressure, blood flow becomes impaired and tissue ischemia occurs. If hypoperfusion and ischemia are not reversed, necrosis of the involved tissue layers will occur. Ischemia will initially present with erythema and induration. If this progresses to necrosis, tissue loss will occur. The duration of critical ischemia varies from patient to patient. However, it is generally

accepted that pressure injury typically occurs between 30 and 240 minutes after hypoperfusion. In patients with preexisting peripheral vascular disease, time to critical ischemia is shorter. Because of impaired arterial inflow, these patients experience significant delay in the restoration of perfusion and reversal of tissue hypoxia after the removal of external pressure. In addition, because of poor underlying tissue perfusion, these patients will experience longer healing times once pressure ulcers develop.

■ CLASSIFICATION

All pressure ulcers begin in the outer layers of the skin. With ongoing pressure, the ischemia progressively extends to deeper layers of the skin. Therefore, pressure ulcers are classified into four stages (stages I-IV) based on the depth of skin involvement, with stage I being the most superficial and stage IV being the deepest. The classification of pressure ulcers is listed in [Table 167-3](#). Having a uniform and well-defined system for pressure ulcer classification is critical for the standardization of wounds during research and for accurate communication on wound staging among health care providers. Once a pressure ulcer develops, it is important to classify the wound and monitor the progress of the wound bed. Having a standard grading system allows for continuity of care and objective monitoring of the progression of the wound.

■ PREVENTION

Prevention of pressure ulcer formation should be standard practice. This is of particular importance when caring for critically ill patients, because they often possess multiple risk factors for pressure ulcer formation.

Risk Assessment

Prevention programs should include initial risk assessment of individual patients. This assessment should include questioning patients on previous or preexisting pressure ulcers; thorough inspection of the skin; evaluation of patients' mobility/activity level, continence, and nutritional status; and a review of comorbid conditions that may contribute to the development of pressure ulcers. Assessment of these risk factors should be standardized and documented. Several tools have been developed for pressure ulcer risk assessment. The Braden Scale assesses external pressure forces and skin-related factors in a standardized manner.⁴ The Norton Scale assesses patient-specific risk factors (age, cognitive impairment, mobility, and incontinence) of pressure ulcer development.⁵ Waterlow Scale, which was initially developed for use in pediatric population, assesses both intrinsic and extrinsic risk factors.⁶ However, studies performed to date have shown limited efficacy of these tools for decreasing the incidence of pressure ulcers compared with nonstructured risk assessment.⁷

Prevention Plan

Once the individual patient risk assessment is performed, a plan for preventing pressure ulcers should be implemented. Regardless of the plan utilized, a frequent assessment of its efficacy must be performed, and any necessary adjustments should be made. The key elements for

TABLE 167-1 Participant Characteristics

preventing pressure ulcer formation include patient mobilization, patient positioning for preventing/removing pressure, and the use of positioning aides to redistribute pressure. In critically ill patients, particularly patients who have been sedated over prolonged periods, prevention of pressure ulcer formation requires vigilance and team effort. Prevention also includes avoidance of skin damage by shear forces and of maceration of the skin due to moisture from incontinence and heat accumulation. Various support surfaces are available for decreasing the

TABLE 167-3 Pressure Ulcer Staging

NATIONAL PRESSURE ULCER STAGING SYSTEM

| | |
|-----------|--|
| Stage I | Non-blanching erythema of the intact skin |
| Stage II | Partial-thickness skin loss involving the epidermis and/or dermis. The ulcer is superficial and presents clinically as an abrasion, blister, or shallow crater. |
| Stage III | Full-thickness skin loss, with damage and/or necrosis of the subcutaneous tissue. The wound extends farther into the skin but not through the underlying fascia. |
| Stage IV | Full-thickness skin loss, with extensive destruction and necrosis of overlying structures, including muscles, bone, or tendon. |

risk of pressure ulcer formation. These pressure-reducing surfaces include static support surfaces (mattresses and mattress overlays) and dynamic support surfaces that mechanically alter the amount of pressure applied to patients' skin. Examples of dynamic support surfaces include low-air-loss beds, air-fluidized mattresses, and alternating pressure mattresses. The use of foam mattress overlays can reduce the risk of pressure ulcer development in high-risk populations.⁸ Although associated with higher costs, dynamic mattresses have not consistently been shown to be superior to static support surfaces. However, dynamic mattresses are superior to standard hospital mattresses in preventing pressure ulcer formation.

TREATMENT

Various treatment options and products are available for managing pressure ulcers. However, very few of the currently available treatment options have been rigorously evaluated in randomized controlled trials.^{9,10} An in-depth discussion of all currently available treatment options is beyond the scope of this chapter; therefore, we have discussed general classes of these treatment options rather than specific products.

Wound Débridement

Wound débridement is a critical step in the healing of pressure ulcers. Débridement removes foreign material and devitalizes tissue from the

wound. After débridement, a wound bed of healthy tissue should be visible. Débridement of the wound bed reduces the production of inflammatory mediators that inhibit wound healing. Various techniques are available for wound débridement, such as surgical débridement, hydrotherapy, larval therapy, and topical enzymatic débridement. The choice of a débridement technique used depends on multiple factors, including size of wound, comorbid conditions, and presence of infection. Surgical débridement is often required in large-volume wounds requiring extensive tissue débridement. However, surgical débridement requires the patient be a suitable candidate for general anesthesia. The risk of subjecting a critically ill patient to general anesthesia and a trip to the operating room must be weighed against the benefits of surgical débridement of a pressure ulcer. Although hydrotherapy is commonly practiced, it has not been evaluated rigorously in large, randomized controlled trials. However, some small studies on patients with stage III or IV pressure ulcers have shown faster wound healing in patients receiving hydrotherapy compared with those not receiving hydrotherapy.^{11,12}

Larval therapy (also referred to as biosurgery) can also be used for debriding pressure ulcers. The basic concept of larval therapy is that application of larvae to wounds results in rapid débridement of necrotic tissues while avoiding potential complications associated with surgical débridement, such as pain and bleeding. Currently, there is evidence that compared to topical enzymatics, larval therapy significantly reduces the time to débridement of necrotic tissue. However, the use of larval therapy did not appear to have any effect on the time to wound healing.¹³

Various topical enzymatic débridement products are commercially available. These can be used alone or in conjunction with other débridement techniques. These agents are applied directly to the wound bed once or twice a day. Multiple randomized controlled trials have validated the efficacy of topical enzymatic débridement products for removing necrotic tissue from the wound bed.¹⁴ Before applying these agents, the wound bed should be cleansed with normal saline. Presence of any topical wound products containing metals will decrease the efficacy of topical enzymatics. Therefore, removing these agents from the wound bed is critical for the success of topical enzymatics. In the event an eschar is overlying the wound bed, it is recommended that the eschar be crosshatched using a surgical blade to allow the penetration of a topical enzymatic agent. Once applied, the wound bed should be covered with gauze. Topical enzymatic agents are a viable and valuable therapy, particularly in patients who cannot undergo alternative débridement methods.

Hydrocolloids

Hydrocolloid dressings that absorb wound exudates are widely used for managing pressure ulcers. Typical hydrocolloid dressings contain a gel-forming agent that is placed in contact with the wound bed, and this is covered with a membrane that protects the wound against external contamination but allows water evaporation.¹⁴ Hydrocolloid dress-

ings are typically applied every 3 to 5 days depending on the amount of exudates produced in the wound. Compared to standard gauze dressings, hydrocolloid dressings are more absorptive and less painful.¹⁴

Negative Pressure Therapy

The use of negative pressure therapy for wound healing has become increasingly common in the past decade. The basic concept behind this therapy is that applying negative pressure to the wound bed both removes edema fluid and increases blood flow to the area. Increased blood flow results in the delivery of oxygen and nutrients, which promote wound healing. In addition, application of negative pressure to the wound results in wound contracture. Compared to standard wet-to-dry dressings, another benefit to patients of negative pressure therapy is decreased frequency of dressing changes. The use of negative pressure therapy for treating pressure ulcers has been associated with improved wound healing and decreased hospital stay.¹⁵ Traditionally, negative pressure therapy has been applied to clean wounds with very less slough or necrotic tissue. However, some evidence indicates that the application of negative pressure therapy is a viable option for managing wounds covered with soft necrotic tissue.¹⁶

Nutritional Support

The presence of malnutrition has a significant impact on wound healing. In fact, its mere presence results in the weakening of the skin and increases the risk of pressure ulcer development. Unfortunately, nutritional assessment is often neglected, particularly in chronically institutionalized patients. Establishing nutritional assessment protocols as well as treating malnutrition is essential for preventing and healing pressure ulcers. This is best accomplished by forming a multidisciplinary team comprising physicians, dietitians, and nursing staff.¹⁷

An initial nutritional assessment should be performed. Any recent weight loss, the current weight, and the patient's dietary intake should all be evaluated. After the initial assessment is completed, a nutrition plan should be created and implemented to address any identified issues. Weekly monitoring of patients' nutritional status, including the patients' weight and functional status, should be performed to determine whether the nutritional intervention is exerting the desired effect. In addition, biochemical tests, including determination of serum prealbumin, transferrin levels, and nitrogen balance, are also helpful.

CONCLUSION

Pressure ulcers continue to be a common problem among critically ill patients. Constant vigilance and education of care providers are essential for preventing pressure ulcer formation. A multidisciplinary approach is needed to manage these debilitating wounds. Management should include objective assessment of the wound, implementation of a multimodality treatment program adapted to patients' needs, and optimization of patients' nutritional status to promote wound healing.

Survival rates and quality have improved dramatically for victims of serious burns in recent decades. For those with smaller burns, the experience and outcome of healing have also improved and moved largely to the outpatient setting. A better understanding of injury physiology, wound healing, and the impact of early surgery for deep injuries has driven these improvements.¹ Burn critical care has evolved to be an essential embedded component of all successful burn programs. This chapter focuses on those aspects of burn critical care that are unique to the care of patients with medium to large burns.²

PHASES OF BURN CARE

Successful management of patients with serious burns requires an effective initial resuscitation and development of an overall plan for acute-phase hospitalization. This care plan can be broken down into four phases (Table 168-1).³ Phase one is the initial evaluation and resuscitation phase. This runs from approximately injury through day 3 and focuses on thorough evaluation for nonburn trauma and accurate fluid resuscitation. The second phase, initial wound excision and biological closure, occupies the first 5-7 days after injury. Major objectives of this phase are clear identification and excision of deep wounds (those unlikely to heal) with immediate permanent or temporary biological closure of generated wounds. This maneuver reduces local and systemic infection and inflammation. In unstable patients or those with large wounds, this may require a series of staged operations. Phase three, definitive wound closure, occupies the ensuing days or weeks and includes replacement of temporary wound membranes with autografts and definitive closure of small complex wounds such as those of the face and hands. Phase four is rehabilitation and reconstruction. This phase can require months or even years in patients with massive burns but is consistent with simultaneous return to work, school, and community. The priorities of this phase of care are functional independence, normalization of life, and emotional well-being.

PHYSIOLOGY OF BURN INJURY

Serious burns are associated with a stereotypical sequence of physiologic changes. Anticipation of these metabolic aberrations facilitates optimal support (see Table 168-1). During the first 1 or 2 days after a serious burn, patients require substantial fluid and hemodynamic support.⁴ If the patient is successfully resuscitated, a hyperdynamic and hypermetabolic state typically ensues. This later phase, characterized by high cardiac output, reduced afterload, fever, and muscle catabolism, must be supported by provision of adequate quantity and quality of substrates. Although this physiology is seen in most seriously injured patients, its intensity and duration are unique to those with larger burns.

Resuscitation Phase

The massive fluid resuscitation required by burn patients is unique in medicine. It is secondary to a diffuse but transient capillary leak driven by poorly characterized mediators.⁵ The clinical result is extravasation of fluids, electrolytes, and even moderate-sized colloid molecules into both burned and unburned soft tissues to a degree not seen in other disease processes. Since the 1930s, a variety of resuscitation formulas have been developed based on burn and patient size. However, this remains an area of clinical art, with no formula being reliably accurate

for all patients.² Factors contributing to varied resuscitation requirements include delay in initiation of resuscitation, inhalation injury, patient age, cardiovascular health, and the depth and vapor transmission characteristics of the wound itself.⁶

Burns under 15% generally do not require a formal fluid resuscitation program. As burn size increases, physiologic aberrations increase in intensity, explaining escalating volume requirements. Burn resuscitation is detailed below.

Hyperdynamic Phase

Typically there is a very noticeable decline in intravenous volume requirements 18 to 24 hours after injury in successfully resuscitated patients as the capillary leak abates. After this hypodynamic period, a systemic hypermetabolic state develops and is sustained in surviving patients until it slowly regresses, well after wound closure.⁷ This state is characterized by high cardiac output, low peripheral vascular resistance, fever, and increased protein flux. In patients not well supported with protein substrate, this increased protein flux will be associated with significant muscle catabolism. This postresuscitation physiology is caused by inflammatory mediators and augmented release of the counterregulatory hormones, cortisol, catecholamines, and glucagon.⁸ These hormonal changes are triggered by a combination of wound- and gut-released bacteria and their byproducts, pain, foci of infection, and some degree of evaporative heat loss.

A central component of burn critical care is to ensure adequate support of the hypermetabolic state. This is done by providing accurate fluid repletion, adequate supplies of metabolic substrates, control of environmental temperature, and competent pain and anxiety control. Early identification and excision of necrotic skin and soft tissue with immediate biological closure of the resulting wounds truncates the hypermetabolic physiologic state and is the most effective way to avoid the deleterious consequences of prolonged hypermetabolism.⁹

Burn critical care requires control of the patient's environmental temperature. Burn patients have enormous and invisible evaporative water and energy losses if they are maintained in the typical cool dry air of a general hospital.¹⁰ Burn units and burn operating rooms must be engineered to maintain high ambient temperature and humidity to avoid the difficult problem of hypothermia and excessive energy loss.

INITIAL EVALUATION AND BURN-SPECIFIC SECONDARY SURVEY

Commonly, when burn patients arrive in the intensive care unit (ICU) where definitive care will be rendered, a complete burn-specific secondary survey has not been completed.¹¹ It is essential for the intensivist to have a familiarity with these issues so burn-related pathology and coexisting injuries are not overlooked. Evaluations should follow the format taught by the Advanced Trauma Life Support course. All seriously burned patients should be approached as having potential multiple trauma.¹²

Initial Evaluation

The primary survey of the burn patient is similar to that of the trauma patient, although there are a few important differences worthy of emphasis. First among these is the progressive mucosal edema that

TABLE 168-1

The Four Phases of Burn Care, with Physiologic Changes and Objectives

| PHASE AND TIMING | PHYSIOLOGIC CHANGES | OBJECTIVES |
|---|--|--|
| 1: Initial evaluation and resuscitation, 0 to 72 h | Massive capillary leak and burn shock | Accurate fluid resuscitation and thorough evaluation |
| 2: Initial wound excision and biological closure, days 1-7 | Hyperdynamic and catabolic state with high risk of infection | Accurately identify and remove all full-thickness wounds and achieve biological closure |
| 3: Definitive wound closure, day 7 to week 6 | Continued catabolic state and risk of nonwound septic events | Replace temporary with definitive covers, and close small complex wounds |
| 4: Rehabilitation, reconstruction, and reintegration, day 1 through discharge | Waning catabolic state and recovering strength | Initially to maintain range of motion and reduce edema; subsequently to strengthen and facilitate return to home, work, school |

may compromise airway patency in the early hours after burns. This is especially true in young children because of their much smaller airway.¹³ Progressive stridor or hoarseness should prompt visualization and/or intubation of the airway. This need is ideally anticipated before the crisis stage so proper equipment and personnel can be gathered, facilitating smooth tube placement. Facial and airway edema can render the burn patient's airway challenging to control. Reintubation can be exceedingly difficult after airway edema has progressed, making unplanned extubation a potentially lethal complication. Security of the endotracheal tube should be regularly assessed. A twill-tie harness is a reliable method of securing the endotracheal tube (Fig. 168-1). Reliable vascular access is also essential for burn resuscitation. In patients with larger injuries, central venous access is often optimal. In emergencies, placing peripheral, central, or intraosseous lines though burns is entirely reasonable. These can be replaced at an unburned site in subsequent hours. Sometimes it is best to wait until volume depletion has been corrected with peripheral lines to more safely place central venous, or especially arterial, catheters.

Burn-Specific Secondary Survey

Supplementing the trauma secondary survey, a burn-specific secondary survey will identify many of the unique clinical problems associated with this type of injury. This should begin with significant past medical history and the circumstances of injury. Important points include details of the injury mechanism, neurologic status at the scene, extrication time, and tetanus immune status. Highlights of the burn-specific secondary survey are described in the following paragraphs.

The ocular and otolaryngologic examination should begin with palpation of the head and face for signs of coincident blunt or penetrating trauma. The globes should be examined prior to the development of facial and eyelid edema, which will limit examination (Fig. 168-2).¹⁴ Serious globe burns impart a clouded appearance to the cornea, and fluorescein staining will detect subtler injuries. Tarsorrhaphy is virtually never indicated acutely, because lid edema will generally provide excellent globe coverage even in the presence of serious lid burns. Pressure on the burned ear and occiput is avoided. Topical mafenide acetate is applied, as it will penetrate the relatively avascular underlying cartilage.¹⁵ Signs of inhalation injury, such as

FIGURE 168-1 ■ A twill-tie harness is a reliable way of securing the endotracheal tube. Protective pads may reduce injury to oral commissures. Tube security should be regularly assessed because reintubation can be very difficult in this setting.

FIGURE 168-2 ■ Globes should be examined early, before development of facial and eyelid edema limits examinations. Serious globe burns impart a clouded appearance to the cornea, and fluorescein staining will detect subtler injuries. Tarsorrhaphy is virtually never indicated acutely, because lid edema will generally provide excellent globe coverage even in the presence of serious lid burns. In some patients, lateral canthotomy, pictured here, can reduce critically elevated intraocular pressures.

carbonaceous debris and singed nasal hairs, are noted on examination of the nose and throat. Ties securing endotracheal and nasogastric tubes should be checked so that pressure on the nasal septum or oral commissures is avoided.

The initial neurologic evaluation centers on exclusion of coincident neurologic injury and control of pain and anxiety. Even if they arrive alert and oriented, patients with serious burns typically become obtunded over the succeeding hours and days, if only because of the effects of pain medications and sleep deprivation. It is therefore important to exclude central nervous system trauma if the mechanism of injury is either unknown or consistent with such trauma. There should be a low threshold for ordering a computed tomographic scan of the head and spine, based on mechanism of injury. Pain and anxiety management should begin during the initial evaluation, within limits of safety.¹⁶ Good pain control may have both physiologic and

FIGURE 168-3 ■ Patients with deep near-circumferential or circumferential chest wall burns may require escharotomy to facilitate ventilation. If properly performed, escharotomy of the torso will markedly enhance compliance.

psychological benefits. In the emergency setting, this is best done with incremental administration of small doses of narcotics and benzodiazepines. When caring for paralyzed or obtunded patients, it is important to make sure there is no pressure on peripheral nerves, so that neuropathies are avoided. Finally, those burned in structural fires should be assessed for carbon monoxide (CO) exposure by history, neurologic examination, and determination of a carboxyhemoglobin level, because selected patients with significant exposure may benefit from hyperbaric oxygen treatment.¹⁷

The cervical spine and neck should be assessed for trauma, based on mechanism of injury. Extremely deep circumferential neck burns may require escharotomy to facilitate normal venous drainage of the head.

The chest wall should be assessed for compliance and symmetric air movement. Patients with deep near-circumferential or circumferential chest wall burns may require escharotomy to facilitate ventilation (Fig. 168-3). If properly performed, escharotomy of the torso markedly enhances compliance.

Most patients are hypovolemic at the time of presentation and respond promptly to volume administration. Some patients, especially the elderly, will have previously unsuspected myocardial disease that may become clinically important during the stress of resuscitation. Some data also support the existence of a myocardial depressant factor in some patients with very extensive injuries.¹⁸ Patients who do not respond as expected to calculated resuscitation volumes may benefit from invasive monitoring, pulmonary artery catheterization, cardiac ultrasonography, and inotropic support.

Genitourinary evaluation is limited in this setting. The foreskin should be reduced over the bladder catheter so paraphimosis is not the result of progressive edema during resuscitation.

Burned extremities should be examined for other trauma, based on mechanism of injury. It can sometimes be difficult to identify fractures in this setting, so liberal use of radiography is appropriate. Fractured and burned extremities are initially stabilized with external splints, prior to placement of external fixators. An essential component of the extremity evaluation is to identify limbs at risk for loss of perfusion with progressive edema during resuscitation and to develop an effective monitoring plan to allow timely decompression should it be needed. Resuscitation-associated edema can cause profound limb ischemia secondary to swelling under a circumferential eschar or within inelastic muscle compartments. This complication is seen in patients who have suffered deep extremity burns (especially if circumferential) or high-voltage electrical injuries. Low-pressure flow in the extremity should be monitored, commonly using a Doppler probe to

FIGURE 168-4 ■ Properly performed escharotomy will result in immediate improvement in extremity blood flow.

FIGURE 168-5 ■ Fasciotomy will release pressure in edematous muscle compartments.

demonstrate flow in the palmar arch or digital vessels, because capillary perfusion pressure is only one-third the mean arterial pressure monitored in larger vessels. Prompt identification of ischemic extremities is essential so that escharotomy (Fig. 168-4) or fasciotomy (Fig. 168-5) can be effected in a timely manner.¹⁹

The wound should not be allowed to interfere with complete evaluation of the patient. Wounds are assessed for extent using a Lund-Browder or other burn diagram, depth by visual examination, and the presence of circumferential components that may require decompression to ensure adequate perfusion. Typically, wounds are underestimated in depth on initial evaluation.

Carboxyhemoglobin and arterial blood gas determinations and screening baseline laboratories are part of the initial evaluation. Chest radiographs are useful to document proper placement of catheters and tubes and the absence of chest trauma. Inhalation injuries typically do not cause early radiographic changes.

Abuse or neglect should be considered when evaluating all burns, not just those in young children. Approximately 20% of burns in young children are reported to state authorities for investigation, but abuse occurs in all age groups.²⁰ Burns can also be a result of domestic violence or other interpersonal assaults. Often this determination is not made until the patient has been admitted to the ICU. Suspicious cases should be filed with appropriate state agencies. Documentation of the stated injury circumstances and of the wounds is essential. Burn diagrams should be carefully completed. Wound photography is ideal in such cases (Fig. 168-6).

FIGURE 168-6 ■ Suspicious cases should be filed with appropriate state agencies. Documentation of stated injury circumstances and of actual wounds is essential; wound photography is ideal. Note flexor-sparing pattern here.

FLUID RESUSCITATION

In the first 1 or 2 hours after a large burn, patients experience little change in intravascular volume or hemodynamics. In fact, patients are often remarkably alert during this period. However, in the hours that follow wound release mediators are released, stress-related hormones are secreted, and reactive oxygen species are formed on reperfusion of marginally perfused tissues. These and perhaps other factors trigger a diffuse loss of capillary integrity, resulting in extravasation of fluid into soft tissues, including those distant to the burn. This remarkable physiologic phenomenon abates 18 to 24 hours later and explains the unique resuscitation needs of patients who have sustained large burns. Predicting resuscitation requirements of specific patients involves multiple variables in addition to burn size, including burn depth, vapor transmission characteristics of the wound, patient age and cardiovascular health, resuscitation delay, environmental temperature and humidity, and presence or absence of concomitant inhalation injury. Numerous formulas have been promulgated to roughly guide resuscitation efforts, but none is accurate in every patient.^{6,21} A common consensus formula is the modified Brooke formula summarized in [Box 168-1](#). Consistent with the military experience of colloid-based trauma resuscitation in recent conflicts, the role of colloid is expanding in burn resuscitation, although this remains an area of ongoing controversy. It is the routine practice of this author to begin 5% albumin at a maintenance rate immediately during resuscitation of patients with larger injuries, subtracting this volume from the crystalloid recommended by formula. I find this reduces the incidence of edema-related complications, including abdominal compartment syndrome.²² Patients not responding as predicted to resuscitation efforts should have serum levels of cortisol checked, particularly if cryptic hypotension, hypernatremia, and/or hypokalemia are also in evidence. Inaccurate fluid resuscitation will cause significant morbidity. Formulas can only help determine initial volume infusion rates and roughly predict 24-hour volume requirements; however, they are so inherently inaccurate that resuscitation should be guided by hourly reevaluation of clinical endpoints. Resuscitation endpoints are summarized in [Table 168-2](#).

BURN CRITICAL CARE ISSUES

Critical care units are embedded in all successful burn programs. Indeed, this is a requirement of the American College of Surgeons–American Burn Association burn center verification program. It is absolutely essential that there is a seamless flow of information and care between critical care and wound management, as the status and

BOX 168-1 Modified Brooke Resuscitation Formula

0-24 HOURS

Adults and children >20 kg

Lactated Ringer's: 2-4 mL/kg/% burn/24 h (first half in first 8 h)

Colloid: none*

Children <20 kg

Lactated Ringer's: 2-3 mL/kg/% burn/24 h (first half in first 8 h)

Lactated Ringer's with 5% dextrose: 4 mL/kg/h

Colloid: none

24-48 HOURS

All patients

Crystalloid: to maintain urine output. If silver nitrate is used, sodium leaching will mandate continued isotonic crystalloid. If other topical is used, free water requirement is significant. Serum sodium should be monitored closely.

Nutritional support should begin, ideally by the enteral route.

Colloid (5% albumin in lactated Ringer's):

0%-30% burn: none

30%-50% burn: 0.3 mL/kg/% burn/24 h

50%-70% burn: 0.4 mL/kg/% burn/24 h

>70% burn: 0.5 mL/kg/% burn/24 h

*Increasingly, early colloid infusion (generally 5% albumin) is being used in patients with very large burns, particularly if they are young or resuscitation is not going smoothly.

Note: The Modified Brooke formula is a common consensus formula that is only useful in individual patients if adjusted to physiologic endpoints. Like all resuscitative formulas, it is a helpful starting point, but optimum-quality resuscitation requires the bedside presence of a physician capable of regularly evaluating resuscitation endpoints.

TABLE 168-2 Age-Specific Resuscitation Endpoints

| RESUSCITATION ENDPOINT | RESUSCITATION TARGET |
|-------------------------|--|
| Sensorium | Comfortable, arousable |
| Physical examination | Warm extremities, full peripheral pulses |
| Urine output | Infants: 1-2 mL/kg/h; children: 0.5-1 mL/kg/h; all others: 0.5 mL/kg/h |
| Base deficit | Less than 2 |
| Systolic blood pressure | Infants: 60-70 mm Hg Children: 70-90 + (twice age in years) mm Hg Adolescents and adults: 90-120 mm Hg |

Note: Age-specific resuscitation endpoints should be assessed regularly throughout burn resuscitation and infusions adjusted up or down in 10% to 20% increments to meet needs of the individual patient.

management of the wound drives most of the patient's systemic derangements. Organizationally, this can be done in two ways. Most commonly and perhaps most cost-effectively, the surgical team managing the wound also manages the critical care. In this schema, burn patients are typically managed in dedicated burn-trauma ICUs, giving the surgeon, nursing, rehabilitation, and support team the volume they need to work effectively. This requires surgeons to be well versed and ideally certified in critical care. The most common alternative to the surgeon-intensivist scheme is to provide critical care in a dedicated area of a general surgical ICU, taking great pains to ensure absolutely seamless flow of information between the surgical and critical care teams. Ensuring this engaged collaborative management is difficult, but it can be done effectively. Seriously burned patients present the critical care team with a set of unique but predictable issues that should be anticipated. A brief review of these follows.

Airway Issues

Although evaluation and control of the airway are part of the initial evaluation, concerns extend throughout the period of intensive care. Endotracheal tube security should be part of the regular reevaluation of every patient in the burn ICU, because facial and hypopharyngeal edema can make reintubation after unplanned extubation incredibly difficult.²³

Inhalation Injury

Inhalation injury remains a clinical diagnosis.²⁴ A history of closed-space fire, the presence of singed nasal hairs and facial burns, and carbonaceous sputum support the diagnosis of inhalation injury. Fiberoptic bronchoscopy can be useful in equivocal cases, as can technetium scanning. However, in the large majority of patients, the diagnosis is made by history and physical examination. The initial chest radiograph is almost always normal, as are gas exchange and compliance until the endobronchial mucosa sloughs several days later, occluding small airways and leading to subsegmental atelectasis and respiratory insufficiency.

Five clinical consequences commonly occur in patients with inhalation injury: acute upper airway obstruction, bronchospasm, small airway occlusion, pulmonary infection, and respiratory failure.²⁵ Airway obstruction and bronchospasm are early complications, typically appearing during the first 48 hours. Airway edema and obstruction are managed with endotracheal intubation. Bronchospasm from aerosolized irritants can be intense during this period but usually respond to nebulized β -adrenergic agonists. Infrequently, intravenous bronchodilators such as terbutaline or low-dose epinephrine infusions are needed. Ventilatory strategies should be designed to minimize “breath-stacking” from auto-PEEP (positive end-expiratory pressure) in this setting.

After 3 to 5 days, sloughing of necrotic endobronchial debris can occur, and pulmonary toilet becomes an increasing problem. Subsegmental atelectasis develops, and shunting intensifies. Frequent suctioning and toilet bronchoscopy can help maintain small distal airway patency.

As many as 50% of patients with inhalation injury will develop pulmonary infection. Differentiating between pneumonia (lobar involvement) and tracheobronchitis (purulent infection of the denuded tracheobronchial tree) is often difficult, but the difference is not really clinically important. Anyone who has fever and newly purulent sputum should be treated with antibiotics, guided by sputum cultures. Pulmonary toilet is particularly important in these patients.

Respiratory failure is unfortunately common in patients with inhalation injury but can generally be managed with a pressure-limited ventilation strategy based on permissive hypercapnia.²⁶ Patients who fail this can sometimes benefit from investigational modes of support such as inhaled nitric oxide or extracorporeal oxygenation, although the utility of the latter is quite limited in burn patients, owing to the need for anticoagulation.^{27,28}

Carbon Monoxide and Cyanide Exposure

Patients injured in structural fires are commonly exposed to high levels of carbon monoxide (CO). Although an obtunded state in this clinical setting can be due to other causes such as intoxication, trauma, or anoxia, hyperbaric oxygen (HBO) has been reported to improve the prognosis of patients who have suffered very severe CO exposure.¹⁹ There are controlled data both supporting²⁹ its use and refuting the utility of HBO,³⁰ so clinical judgment must be brought to bear in the decision whether to use this form of therapy in individual patients.

CO binds and inactivates heme-containing enzymes such as hemoglobin and the cytochromes. The binding of CO and hemoglobin forms carboxyhemoglobin, which does not deliver oxygen, resulting in acute physiologic anemia, much like an isovolemic hemodilution. A serum carboxyhemoglobin level of 50% is similar to an isovolemic

hemodilution to 50% of the baseline hemoglobin concentration. This level of carboxyhemoglobin results in unconsciousness, implying that other mechanisms are also involved in the pathophysiology of CO injury. CO binding to the cytochrome system in the mitochondria probably interferes with oxygen utilization. Approximately 10% of patients with severe CO exposure have been reported to develop severe delayed neurologic sequelae.³¹

There are two practical treatment options: 100% normobaric oxygen or HBO. There are well-designed clinical studies both supporting and refuting the utility of HBO for CO poisoning.^{29,30} Proponents cite a decreased incidence of delayed neurologic sequelae in those treated with HBO. In patients with very severe CO poisoning with either very high carboxyhemoglobin levels or neurologic impairment not otherwise explainable, HBO is probably warranted if it can be safely administered. Relative contraindications to HBO are wheezing or air trapping, which increase the risks of pneumothorax or gas embolism, and high fever, which increases the risk of seizures. Before placement in the chamber, endotracheal tube balloons should be filled with saline to avoid balloon compression–associated air leaks, and upper body central venous cannulation should be avoided if possible to avoid sudden enlargement of an occult pneumothorax during decompression.³²

Hydrogen cyanide is detected in the smoke from many structural fires and in the serum of some burn patients. At a high enough concentration, cyanide causes failure of oxygen utilization at the cytochrome level, with a secondary unexplained metabolic acidosis. Cyanide poisoning can be treated with amyl nitrate and sodium thiosulfate.³³ However, cyanide is rapidly metabolized in resuscitated patients, making specific treatment generally not necessary or useful.

Pain and Anxiety Management

Undertreatment of pain and anxiety was very common in the past, and burn intensivists need to pay particular attention to this issue. Reasons for undertreatment are related to the extraordinary drug doses required to adequately address pain in seriously burned patients and consequent fear of respiratory depression, addiction, and litigation. The opiate and benzodiazepine tolerance of patients with large open wounds is truly remarkable. Once wounds are closed, drug needs rapidly decrease, and addiction is rare. The best way to eliminate burn pain is prompt wound closure.

Unfortunately, control of pain and anxiety is very difficult in burn patients. Successful management is greatly aided by a set of guidelines. One such program addresses four clinical states: intubated acute, non-intubated acute, chronic acute, and reconstructive patients.³⁴ Within each clinical state are separate guidelines for background pain, background anxiety, procedural pain, procedural anxiety, and transition to the next clinical state. Attention to the issue has physiologic as well as obvious psychological benefits. Reduced secretion of catecholamines may decrease systemic hypermetabolism, and treatment-related acute stress is reduced. If doses of benzodiazepines and opiates are excessive, a number of alternative drugs have proven useful, particularly dexmedetomidine, which is not a respiratory depressant and has proven particularly valuable during weaning and extubation.^{35,36}

Ocular Issues

In the first 72 hours of resuscitation, rare patients will develop retrobulbar edema and intraocular hypertension that may benefit from decompression (see Fig. 168-2). Typical patients are those with large surface area burns with deep facial involvement. The diagnosis is made with tonometry. Treatment is by lateral canthotomy, a procedure that can be performed at the bedside with immediate reduction in pressure and normalization of retinal blood flow.

Contraction of burned eyelids and facial skin can cause exposure of the globe in the days or weeks after burns.¹⁵ If unchecked, this will result in exposure and then desiccation of the globe, with secondary keratitis and corneal ulceration. Infected corneal ulcers rapidly lead to

globe perforation because the cornea is almost avascular and tolerates desiccation and infection very poorly. When minimal or moderate, globe exposure can be managed with frequent ocular lubrication. Acute eyelid release should be done promptly if exposure is severe or keratitis does not resolve with lubrication over a few days.

Peripheral Neuropathies

Peripheral neuropathies are more common than is usually appreciated in burn patients.^{37,38} They can be caused by direct thermal damage to peripheral nerves or by the many metabolic disturbances seen during acute burn care. A minority of these lesions are caused by constricting eschar, compartment syndrome, or improperly filled splints. Extremities at risk should be monitored for compartment syndrome and constricting eschar. These issues are best addressed surgically as early as possible. Heavily sedated patients or those under general anesthesia in the operating room should be examined to make sure that traction and pressure injuries are avoided.

Gastrointestinal Issues

Curling's ulcers were a common cause of massive upper gastrointestinal bleeding in the past. This is now an infrequent occurrence with better resuscitation, which decreases splanchnic ischemia. Routine use of prophylactic gastric alkalization has also been important. Patients with serious burns should be treated with empiric histamine-receptor blockers, proton-pump inhibitors, and/or antacids until they are tolerating tube feedings and are at low enough risk that this therapy can reasonably be stopped. Calculous or acalculous cholecystitis in the critically ill burn patient is easily missed and can be the cause of significant illness. Fevers are often assumed to be secondary to the wound. Cholestatic blood chemistry values and modest clinical jaundice are identical to the changes that typify hepatic insufficiency. If untreated, gangrenous cholecystitis associated with peritonitis and sepsis can result. Diagnosis is easily made by bedside ultrasonography. Treatment can be either by laparoscopic or open cholecystectomy. In the critically ill patient, percutaneous transhepatic drainage is a very reasonable alternative.³⁹

Although uncommon, pancreatitis is a reported complication seen in patients with very large burns.⁴⁰ Like cholecystitis, it is easily missed until the condition is far advanced. Abdominal distention and ileus, with tenderness in those who are conscious, should prompt measurements of serum amylase and lipase concentrations as well as appropriate abdominal imaging in selected cases. Most patients can be treated with bowel rest, although pseudocysts and abscesses have been reported in this population.

Bowel ischemia and necrosis are complications generally seen in those with prolonged burn shock, often part of a delayed resuscitation syndrome. These complications present as ileus and then peritonitis. Bowel necrosis is lethal unless operated on promptly. It is a frequently reported autopsy finding in patients dying of burns.^{41,42}

Superior mesenteric artery syndrome is a rare occurrence but should be seriously considered in patients with major weight loss during the acute phase of injury, who then develop intractable vomiting in the recovery phase of their illness. It is due to compression of the duodenum in the angle between the aorta and superior mesenteric artery.⁴³ Diagnosis is by barium swallow, and treatment is a combination of parenteral nutrition and tube feedings past the point of obstruction if possible.

Finally, it is easy to miss more common abdominal pathology in the setting of burns. Appendicitis can be a lethal complication first diagnosed at autopsy. Constipation from narcotic use and inactivity is common and is ideally prevented with a bowel regimen.

Nutritional Support

Burn patients need accurate energy and protein support. Underfeeding and overfeeding have adverse sequelae. Ideally, tube feedings are begun

during resuscitation.⁴⁴ Most patients do well with continuous intragastric tube feedings, although some require postpyloric feedings.⁴⁵ Enteral nutritional support can be started through a nasogastric sump tube so that gastric residuals can be used to help determine tolerance of the feedings initially.⁴⁶ Parenteral support is useful during periods when ileus is likely, such as during septic episodes or periods when high-dose vasopressor support is needed, or during the perioperative period. Transient parenteral support can be particularly important in hypermetabolic young children who are very catabolic and do not tolerate prolonged periods of fasting.

Goals for nutritional support for burned patients are controversial. Consensus recommendations include approximately 2.5 g/kg/day of protein with a nonprotein caloric load between 1.5 and 1.7 times the calculated basal metabolic rate or 1.3 and 1.5 times the measured (by indirect calorimetry) resting energy expenditure.^{47,48} Nutritional support should be adjusted throughout the illness, based on specific endpoints. The role of anabolic agents in burn patients has been an area of controversy for two decades. Currently, many programs advise the use of anabolic steroids in particularly nutritionally depleted patients, watching carefully for hepatic complications. Serial physical examination, quality of wound healing, nitrogen balance, and indirect calorimetry can be integrated to assess the adequacy of support and help fine-tune the predictions of nutritional equations.

Infectious Disease Issues

Through loss of skin, necrosis of the endobronchial epithelium, and invasive devices, serious burns impair the host's physical barriers to bacteria while interfering with immune function. Therefore, burn patients are prone to virulent infectious complications. Anticipation of these infections will help minimize infectious morbidity and mortality.

Historically, wound sepsis has been the great killer in burn units, and burn wound infections remain surprisingly common today.⁴⁹ Diagnosis of wound sepsis is generally clinical, based on signs and symptoms of systemic infection along with changes in wound appearance. The diagnosis can be supported by wound biopsy and quantitative cultures, but both of these diagnostic techniques are infamously inaccurate, making a clinical diagnosis the most reliable.⁵⁰

The best way to prevent wound sepsis is to identify and excise deep burns within the first few days after injury and to close the resulting wounds. Topical agents are only an adjunct to this effort and cannot on their own be relied upon to prevent wound sepsis but can delay the onset of sepsis in deep wounds. They can also serve to minimize desiccation and colonization of healing wounds. There are several agents in wide general use; the most common are listed in Table 168-3. All have specific advantages and disadvantages. Use of aqueous silver nitrate commonly promotes development of hyponatremia and hypokalemia. Use of mafenide acetate, which inhibits carbonic anhydrase, leads to the development of metabolic acidosis, making it more difficult to use permissive hypercapnia for the management of patients with severe respiratory failure. Silver sulfadiazine application leads to large losses of free water across the burn wound eschar. The use of

TABLE 168-3 Topical Agents Used in Wound Management

| AGENT | CHARACTERISTICS |
|---------------------|---|
| Silver sulfadiazine | Painless on application, fair to poor eschar penetration, no metabolic side effects, broad antibacterial spectrum |
| Mafenide acetate | Painful on application, excellent eschar penetration, carbonic anhydrase inhibitor, broad antibacterial spectrum |
| 0.5% Silver nitrate | Painless on application, poor eschar penetration, leaches electrolytes, broad spectrum (including fungi) |

silver-impregnated membrane dressings has increased markedly in recent years, although primarily in the outpatient setting with smaller burns. Program-specific use in inpatients is becoming increasingly common. As with all membrane dressings, fever or other signs of potential sepsis should prompt membrane removal and wound examination.

Antibiotic use must be focused. Too-liberal empiric use will lead to development of resistant organisms. Burn physiology, in the absence of infection, includes fever and a hyperdynamic circulation. When systemic infection is suspected, a careful physical examination and wound inspection should be done and cultures taken, particularly of blood, urine, and sputum. If the patient is hypotensive or otherwise unstable, it is reasonable to start a short course of empiric antibiotic treatment while awaiting return of blood cultures. Clinical deterioration of the burn patient is most often related to infection.

Infection-control practices should be routine and relatively rigid in burn units. This patient population has a high incidence of infection in general, and resistant bacterial species are very common. Universal precautions should be practiced in all patients. The use of prophylactic antibiotics is not advised.⁵¹

Rehabilitation Therapy in the Burn Intensive Care Setting

Physical and occupational therapists should be involved from the outset and strategies implemented to avoid common contractures that will otherwise interfere with recovery later (Table 168-4). Early tasks include passive movement of all joints through an appropriate range of motion and static positioning in ways that minimize the risk of deformity. This progresses through active exercise and strengthening, which greatly speeds recovery. This is time-intensive therapy that requires many hours of therapist involvement to be successful, particularly after protracted critical illness.^{13,52}

Intraoperative Critical Care

Often, burn patients must be subjected to stressful operative procedures to excise and close wounds, even during periods of critical illness and hemodynamic instability. They can only survive these interventions if critical care efforts are continued during the operations. There must be continuous communication between the surgical and anesthesia teams during surgery. Each team must understand what the other is doing and is about to do, so it can anticipate its own next interventions.

Intrahospital transport from the protected environment of the ICU to the operating room must be carefully planned, and skilled people should accompany the patient during transport. Burn patients have huge evaporative heat losses that can rapidly render them hypothermic unless the operating room is kept warm and core temperature is continuously monitored. Hypothermia promotes development of

coagulopathy, which can complicate these operations. The intensive care team should be involved in operative events.

SPECIAL INJURY CONSIDERATIONS

Burn units have a unique set of resources: critical care expertise, complex wound care and closure skills, and strong rehabilitation programs. This resource set benefits other nonburn injuries and illnesses that are increasingly referred to burn programs for primary therapy. The most common injuries involve electrical, chemical, tar, cold, and soft-tissue trauma and infections. The most common illnesses are toxic epidermal necrolysis (Fig. 168-7) and purpura fulminans.

Electrical Injury

Electrical injuries are commonly divided into low voltage ([household] 110-220 volts), intermediate voltage (220-1000 volts), and high voltage (>1000 volts) exposures. Patients with good electrical contact to low and intermediate voltage sources can suffer severe local wounds but rarely manifest systemic consequences such as compartment syndromes or rhabdomyolysis.⁵³ Patients with good contact to high voltages commonly have compartment syndromes, myocardial injury, fractures of the long bones and spine, and free pigment in the plasma that may cause renal failure if not promptly cleared.^{54,55} These patients can also manifest deep arching wounds, flash burns, and thermal burns from clothing ignition. Such patients can also sustain blunt trauma during the incident, most commonly from falls.

FIGURE 168-7 ■ The cause of toxic epidermal necrolysis remains a mystery. This patient has both a cutaneous and a visceral wound.

TABLE 168-4 Common Contractures and Prevention Strategies Useful in the ICU

| ANATOMIC AREA | COMMON CONTRACTURE | ICU PREVENTIVE SPLINTING AND POSITIONING STRATEGY |
|----------------------------|-----------------------|---|
| Neck | Flexion | Daily range-of-motion exercises and extension splinting and conformers; split mattress |
| Shoulder | Adduction | Daily range-of-motion exercises and abduction splinting with axillary splints or troughs |
| Elbow | Flexion and extension | Daily range-of-motion exercises and alternating extension and flexion splints |
| Wrist | Flexion and extension | Daily range-of-motion exercises and splinting in functional position (20 degrees of extension) |
| Metacarpophalangeal joints | Extension | Daily range-of-motion exercises and splinting in functional position (metacarpophalangeal joints at 70 to 90 degrees of flexion, all interphalangeal joints in extension, first web space open, wrist at 20 degrees of extension) |
| Hips | Flexion | Daily range-of-motion exercises and extension splints and prone positioning (if tolerated) |
| Knees | Flexion | Daily range-of-motion exercises and knee splints and knee immobilizers |
| Ankles | Extension | Daily range-of-motion exercises and neutral splints |
| Metatarsophalangeal joints | Extension | Daily range-of-motion and splinting in functional position; rocker-bottom shoes |

After high-voltage exposures, cardiac monitoring is a good idea for 24 to 72 hours. Urine should be examined grossly for pigment after placement of a bladder catheter. Fluid resuscitation should be started based on surface burn size, but this usually does not correlate well with deep tissue injury, so resuscitation must be closely monitored and titrated to the patient's physiology. Compartment syndromes are common, and this should be considered. Compartments at risk should undergo serial reexamination and be decompressed when an evolving compartment syndrome is suspected. Wounds associated with the injury are excised and closed in the following days with a combination of skin grafts and flaps.

Cold Injury

Cold injuries often generate wounds best cared for in the burn unit; initial management is usually conservative. Early management of hypothermia is a priority. Frozen tissues are thawed with body-temperature water. Necrotic tissue is excised when demarcation is clear, and the resulting wounds are grafted or closed with flaps. If patients present with ischemic extremities with less than 24 hours of warm ischemia time, diagnostic angiography may be considered in selected stable patients. If there is no flow despite intraarterial vasodilators, thrombolytic therapy may be appropriate.⁵⁶

Chemical and Tar Injury

Chemical injuries can be associated with both local and systemic effects. Poison control centers should be consulted liberally if there is a question of systemic toxicities. It is essential to protect staff from exposure to the chemicals during removal. Most agents can be irrigated off with tap water for 30 minutes, although alkaline substances may take longer. When the "soapy feeling" alkaline substances often impart to the gloved finger is gone, or when litmus paper indicates a neutral pH, irrigation may be stopped. Hydrofluoric acid, especially in concentrated form, may result in severe acute hypocalcemia because the fluoride anion strongly binds divalent cations.⁵⁷ Subeschar injection of 10% calcium gluconate and/or immediate excision of the wound may be lifesaving. Elemental metals such as solid lithium or sodium can ignite on contact with water or air and should therefore be covered with oil. White phosphorus, a component of many munitions, will also ignite on contact with air, and wound particles are ideally covered with wet cloth or gauze. A number of road-surfacing materials are viscous and heated up to 700°F for application. They are designed to stay solid in the hot sun on dark pavement. When these materials splash road workers, the wounds should be quickly cooled by tap water irrigation. Wounds should be soaked in a lipophilic solvent after cooling and then be debrided and grafted as indicated by burn depth, which is often quite deep.

CONCLUSION

Patients with serious burns present a unique suite of challenges to the ICU team that cross multiple disciplines. Long-term outcome data support the contention that most survivors of serious burns will ultimately have a very satisfying quality of life, making the ICU efforts

worthwhile.⁵⁸ Successful outcomes require a coordinated effort by intensivists, surgical, nursing, and rehabilitation therapy professionals during what can be technically and emotionally demanding, but ultimately rewarding ICU stays.

KEY POINTS

1. Burn care can be divided into four clinical phases: initial evaluation and resuscitation, initial wound excision and biological closure, definitive wound closure, and rehabilitation and reconstruction.
2. Postresuscitation physiology is characterized by high cardiac output, reduced afterload, moderate fever, and muscle metabolism.
3. Burn units and burn operating rooms should be engineered to maintain high ambient temperatures to avoid hypothermia and energy loss.
4. The burn-specific secondary survey must often be completed in the ICU.
5. Monitoring and early identification of extremity ischemia secondary to overlying eschar or tight compartments is essential.
6. The wound should not distract examiners from a thorough and complete patient evaluation.
7. No standard resuscitation formula is accurate in an individual patient. Patients must be resuscitated using resuscitation endpoints.
8. Patients with inhalation injuries typically have normal chest radiographs and near-normal gas exchange and compliance early on. Over the 3 to 7 days after injury, significant pulmonary dysfunction may occur.
9. The best way to reduce burn wound pain is prompt wound closure.
10. Exposure of the globe must be anticipated and managed to preserve vision.
11. Early nutritional support is essential in light of postresuscitation physiologic changes. This is ideally accomplished enterally, but parenteral support is also safe when properly administered.
12. Physical and occupational therapy should begin from the outset of burn care.
13. Intensive care management of the patient should proceed throughout operations.
14. Patients with toxic epidermal necrolysis have both a cutaneous and a visceral wound.

ANNOTATED REFERENCES

- Zonies D, Mack C, Kramer B, Rivara F, Klein M. Verified centers, nonverified centers, or other facilities: a national analysis of burn patient treatment location. *J Am Coll Surg* 2010;210:299–305.
These authors examined a large database including 29,971 burn patients treated in 1376 hospitals located in 19 participating states over a 2-year period. They noted that many patients meeting burn center criteria continue to be managed in non-burn center facilities, implying that further cost savings and enhanced results may be realized with increasing regionalization.

Thoracic trauma is responsible for approximately 20% of all trauma-related deaths and is second only to central nervous system injury as the primary cause of death at the scene. For patients arriving at the emergency department (ED) alive, rapid diagnosis and treatment of potentially life-threatening injuries are required to prevent death during the “golden hour” of initial resuscitation. However, many thoracic injuries that are not immediately life-threatening still have the potential for significant morbidity and mortality. The following is an overview of the diagnosis and management of thoracic trauma.

■ INITIAL ASSESSMENT

Primary Survey

The Advanced Trauma Life Support (ATLS) course of the American College of Surgeons Committee on Trauma¹ provides basic tenets for the management of injured patients. The process begins with the primary survey, a stepwise evaluation of the “ABCs”: Airway, Breathing, and Circulation.

Airway patency may be compromised by neurologic injury, facial injury, or obstruction (e.g., by tongue, blood, vomitus, tooth or bone fragments). Trauma to the larynx, trachea, or bronchus may also complicate or preclude airway control. Thoracic trauma may also cause life-threatening breathing (e.g., pneumothorax, pulmonary contusion) and circulation (e.g., tension pneumothorax, pericardial tamponade, massive hemothorax) problems. These must be identified and treated rapidly.

Resuscitative Thoracotomy

Resuscitative thoracotomy (RT) is indicated for traumatic cardiac arrest or persistent severe hypotension (e.g., systolic blood pressure [SBP] <60 mm Hg). The primary objectives of RT are to (1) release pericardial tamponade and repair cardiac injuries, (2) control intrathoracic hemorrhage, (3) control bronchovenous air embolism or bronchial injury, (4) perform open cardiac massage, and (5) attenuate subdiaphragmatic hemorrhage and redistribute blood flow to the brain and myocardium.² The critical determinants of survival following this procedure are the mechanism of injury and the patient's condition. The best outcomes are seen in adult patients with isolated penetrating cardiac injuries who present with detectable SBP; survival averages 35% in large series. In contrast, RT is least beneficial in the treatment of blunt injury without signs of life, with only 1% to 2% of patients surviving.

An algorithm for resuscitation of moribund trauma patients is presented in [Figure 169-1](#).² Patients arriving in extremis following blunt injury undergo thoracotomy if they have had fewer than 10 minutes of cardiopulmonary resuscitation (CPR). Penetrating trauma victims undergo thoracotomy if they have had fewer than 15 minutes (for torso injuries) or 5 minutes (nontorso injuries) of CPR. The pericardium is opened; if there is no organized cardiac activity and no blood in the pericardium, the patient is pronounced dead. Otherwise the descending thoracic aorta is occluded to limit subdiaphragmatic hemorrhage and redistribute perfusion to the myocardium and brain. Patients who do not respond with SBP >70 mm Hg are pronounced dead on the basis of futility. The value of thoracotomy in the resuscitation of a

patient in profound shock is unquestioned. Its indiscriminate use, however, is not appropriate. While the performance of RT only “costs” the price of a scalpel and sterilization of the instrument tray, it is critical to recognize futility and avoid initiating massive transfusion or transferring the patient to the operating room (OR). These resources should be reserved for potential survivors. Furthermore, while no cases have been specifically reported, there is a potential risk of transmission of blood-borne disease to the health care team. Finally, the use of Resuscitative Endovascular Balloon Occlusion of the Aorta (REBOA) has been proposed in this setting. Because open-chest CPR has been proven superior in the setting of hypovolemia, and REBOA placement may exacerbate thoracic hemorrhage, it is not recommended at this time.³

■ PLEURAL SPACE

Pneumothorax

Pneumothorax (PTX) is common in thoracic trauma. Decreased breath sounds and hyperresonance to percussion are not 100% accurate. Chest x-ray (CXR) has long been considered the diagnostic standard, but the extended focused assessment with sonography for trauma (E-FAST) has potentially greater sensitivity for a small PTX in the supine patient. If not relieved, a PTX may progress to a tension PTX, especially if the patient is receiving positive-pressure ventilation. In this setting, the mediastinal structures are shifted away from the affected side. Once venous return to the heart is impaired, cardiovascular collapse ensues. Immediate decompression of tension PTX can be lifesaving.

An open PTX, a.k.a. “sucking chest wound,” results from a full-thickness chest wall wound. If the wound diameter exceeds two-thirds of the tracheal diameter, negative intrapleural pressure associated with inspiratory effort results in air entering the pleural space preferentially through the wound. Because of the large hole, there is little chance of tension. However, this can be life-threatening because it prevents pulmonary gas exchange. It is managed by an occlusive dressing secured on three sides to prevent sucking of more air but allowing decompression of the pneumothorax until definitive wound closure and tube thoracostomy can be performed.

With the growing use of thoracic computed tomography (CT), small PTXs are often discovered that are not seen on CXR. These “occult PTXs” generally do not require treatment but should be monitored for progression. A recent prospective multicenter study of the American Association for the Surgery of Trauma (AAST) found that only 6% of patients with occult PTX ultimately required a chest tube. Moreover, consistent with earlier studies, fewer than 20% receiving positive-pressure ventilation required chest tubes, and none of them had tension.⁴

Tube Thoracostomy

Tube thoracostomy is the definitive treatment for PTX and hemothorax. The procedure is not difficult and can be performed rapidly, but care must be taken to avoid malpositioning. The optimal position is posterior, to facilitate dependent drainage of blood, and directed to the apex of the pleural cavity. The current trend is to place smaller diameter tubes, as they cause less discomfort for the patient and are adequate to drain most nonclotted hemothoraces.⁵

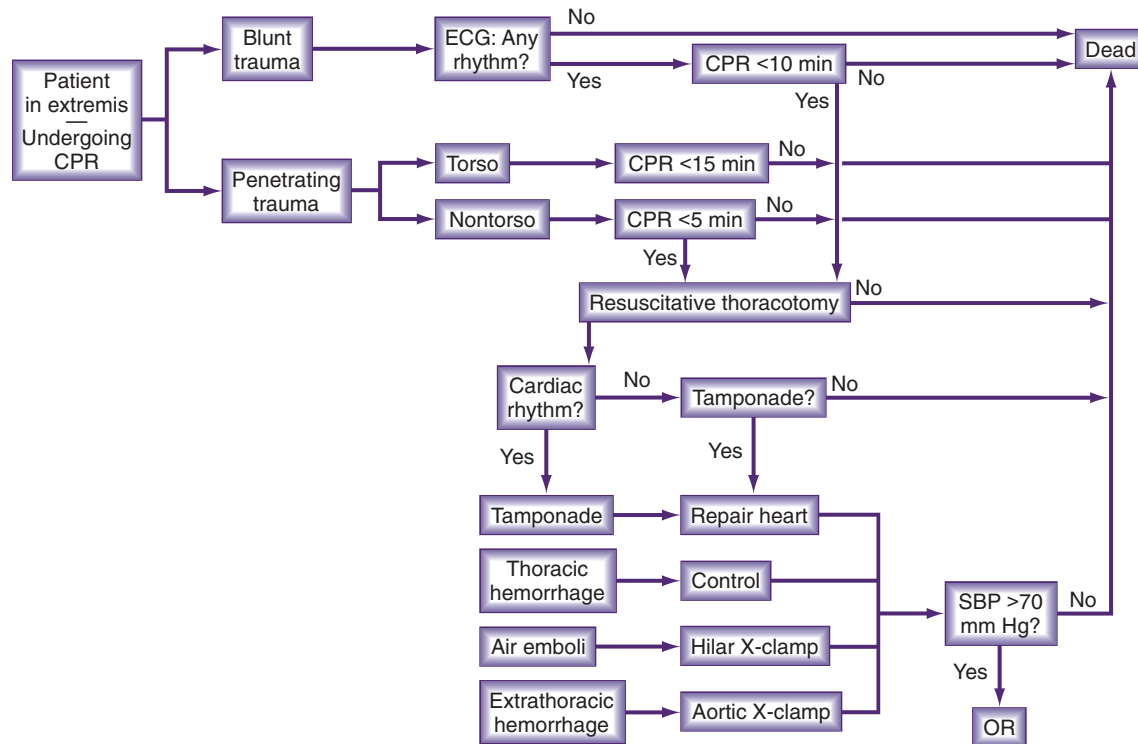

FIGURE 169-1 ■ Algorithm for resuscitative thoracotomy.

In the setting of tension PTX, if tube thoracostomy is not immediately available, the chest can be quickly decompressed with a large-bore needle. Although many authors previously promoted needle thoracostomy via the second intercostal space in the midclavicular line, it has been recognized repeatedly that catheters may be kinked in the pectoralis major muscle or breast tissue, rendering them ineffective—often unbeknownst to the clinician. Recent literature has documented that the anterior axillary line in the fifth intercostal space is, on average, 10 to 12 mm thinner. This site allows rapid, reliable, safe entry into the pleural space.⁶

In the past, some investigators proposed routine prophylactic antibiotics to prevent infections related to tube thoracostomy. However, prophylactic antibiotics do not reduce the incidence of empyema or pneumonia and may be associated with antimicrobial resistance in subsequent hospital-acquired infections.⁷

Pneumothoraces and air leaks should be resolved before removal of the tube, and ideally, drainage should be less than 2 mL/kg/d. After 12 to 24 hours without an air leak, the tube may be removed while on suction. However, a 6- to 12-hour trial of waterseal drainage is generally warranted to observe for an occult air leak.⁸ It has been recommended that tubes be removed at maximal deep inspiration with a Valsalva maneuver, but recurrent PTX may occur in 6% to 8% of patients regardless of respiratory phase. More than 20% of patients require longer than 3 days to resolve an air leak, in which case their hospital course may be expedited by the use of thoracoscopy.⁹

Hemothorax

Blunting of the costophrenic angle on upright CXR requires 200 to 250 mL of blood, and in a supine patient, there may be only subtle haziness of the affected hemithorax. Large hemothoraces should generally be drained by tube thoracostomy, but hemothoraces that are asymptomatic and seen only on CT can be managed expectantly. A massive hemothorax is usually the result of a major vascular injury and is life-threatening. Indications for thoracotomy include the immediate

return of 1500 mL of blood via tube thoracostomy, or continued output of more than 200 mL/hr for 2 to 3 consecutive hours. The clinician should be wary of an initial high-volume output that is followed by an abrupt decrease in volume. In this case, a repeat CXR should be obtained to rule out a “caked hemothorax.” If the original tube appears to be well positioned and there is significant retained hemothorax, thoracoscopy or thoracotomy is indicated. Hemothoraces associated with massive blunt chest wall trauma can pose special challenges. Ongoing bleeding suggests the need for thoracotomy, but a large incision may compound the bleeding, and diffuse bleeding from bone and soft-tissue disruption may prove difficult to control. In this setting, one might consider arteriography with embolization of intercostal vessels in a hemodynamically stable patient.

■ CHEST WALL INJURY

Rib Fracture

Rib fractures are very common. Rib fractures in elderly patients can lead to diminished pulmonary function with potentially disastrous complications. Patients over the age of 65 have two- to fivefold increases in morbidity and mortality compared with younger patients with similar injuries.^{10,11} A key factor in the management of these patients is pain control to facilitate coughing and clearance of secretions. Epidural catheters have proved to be efficacious and superior to patient-controlled analgesia in this regard and may also modify the immune response.^{12,13} Rib blocks may provide immediate relief in the ED or intensive care unit (ICU) while awaiting epidural catheter placement. A paravertebral catheter provides another alternative; current investigations are designed to determine whether this intervention may supplant epidural catheters.¹⁴

Flail Chest

Two or more ribs fractured in two or more places produce a flail segment of the chest wall. This segment may move paradoxically—

inward during inspiration, outward during expiration—and consequently impair respiratory mechanics. However, a more important cause of respiratory compromise following flail chest is the pulmonary contusion that typically accompanies it. Treatment is supportive, including supplemental oxygen, analgesia, and pulmonary toilet. Surgical stabilization of the flail segment and rib fracture repair in general has been performed for many years without clear demonstration of benefit or identification of the patient population most likely to benefit. Recent modifications in instrumentation and technique have made this potentially more efficacious¹⁵; a recent prospective study suggested benefits in terms of respiratory function, need for mechanical ventilation, and length of stay.¹⁶ However, identification of the patient most likely to benefit remains an issue.

Sternal Fracture

Early series of sternal fractures described the “steering wheel syndrome” (rapid deceleration, with impact of the sternum on the steering wheel) as the most common cause of sternal fractures. Associated blunt cardiac injury was common, so sternal fractures were thought to be harbingers of significant thoracic injury. More recently, however, sternal fractures have been reported more commonly with the “seat belt syndrome” (in conjunction with three-point or bandolier seat belts). Associated injuries are less frequent, so stable patients without ECG abnormalities can be safely discharged from the ED.

LUNG INJURY

Pulmonary Contusion

Pulmonary contusion is common following major chest trauma. The pathophysiologic changes fundamentally include hemorrhage with surrounding edema, with a broad range of severity. The clinical result is hypoxia and increased work of breathing due to ventilation/perfusion mismatching and decreased pulmonary compliance. Pulmonary contusions may not appear on initial chest radiographs, although they are usually seen by 6 hours after the injury; chest CT is more sensitive at diagnosing early pulmonary contusions. Treatment is supportive, including supplemental oxygen, pain control, pulmonary toilet, and judicious fluid management. There is no role for either routine antibiotics or steroid therapy.¹⁷ Intubation and mechanical ventilation are employed only as necessary. The degree of pulmonary dysfunction can peak at 72 hours and generally resolves within 7 days in the absence of associated nosocomial pneumonia.

Posttraumatic pulmonary pseudocysts are cavity lesions that occur in approximately 3% of lung parenchymal injuries.¹⁸ They are often noted incidentally on the chest radiograph. Most resolve spontaneously within 2 to 4 months. However, surgical intervention is indicated for infection, bleeding, and rupture. The lesion can be distinguished from an abscess by CT-guided aspiration.

Pulmonary Laceration

The typical clinical presentation is a hemopneumothorax. Bleeding is usually self-limited, and the vast majority of these injuries are definitively managed by tube thoracostomy alone. Of the 10% of patients requiring thoracotomy, approximately 20% need lung resection. Historically, this group has experienced high morbidity and mortality, with mortality following pneumonectomy approaching 100%. In 1994, Wall and colleagues introduced the concept of pulmonary tractotomy as a nonresectional means of managing penetrating lung injuries.¹⁹ It is indicated for deep through-and-through injuries that do not involve central hilar vessels or airways. The wound tract is exposed by passing clamps (as originally described) or a stapling device (our preference) through the wound and dividing the bridge of lung tissue. Air leaks and bleeding points are sutured, and the wound tract is left open. Morbidity and mortality compare favorably with anatomic resections.²⁰

Mediastinal Injuries

Pneumomediastinum

Pneumomediastinum has classically been considered a sign of aerodigestive injury, particularly when seen on CXR; however, with expanding use of chest CT, pneumomediastinum is seen with increasing frequency. Recent analyses have found that pneumomediastinum is present on approximately 5% of chest CT scans following trauma but that only 10% of these patients actually have aerodigestive injuries.²¹ In the absence of signs or symptoms or additional suspicious findings on CT scan, further investigation is not necessary.

TRACHEOBRONCHIAL INJURY

Tracheobronchial injuries are uncommon but should be excluded in the presence of cervical subcutaneous emphysema, pneumomediastinum, or pneumothorax with a persistent air leak. The definitive diagnostic test is bronchoscopy. Cervical injuries are approached via cervical incisions, with partial or complete sternotomy as needed. Blunt injuries often occur in the distal trachea or right mainstem bronchus and are approached via right thoracotomy. Tracheal injuries can usually be repaired primarily or by resection and reanastomosis without tracheostomy; late stenosis is uncommon. On the other hand, laryngotracheal injuries often require tracheostomy as an adjunct to repair, and tracheal stenosis is a common late complication. Absorbable monofilament sutures are preferred. Bronchial injuries may be repaired, but severe disruptions or associated vascular injuries may necessitate pneumonectomy or lobectomy. Positive end-expiratory pressure is avoided postoperatively.²²

ESOPHAGEAL INJURY

Esophageal perforation from blunt force trauma is a rare event caused by a sudden rise in intraluminal pressure or by the upper esophagus being crushed between the trachea and a vertebral body. More commonly, esophageal injury is the result of penetrating trauma. Early signs and symptoms of injury can be subtle. Pneumomediastinum should prompt consideration of this injury. Barium esophagography is considered the diagnostic study of choice and can be readily obtained in a stable, awake patient. However, videoendoscopy can be done at the bedside virtually anywhere in the hospital and has excellent accuracy. Thus, it is preferred in critically ill or unstable patients in the ICU or operating room.²³

If the injury is identified within 24 hours, it can usually be treated with débridement, primary repair, and drainage. If a tension-free repair is not possible, it is best managed with débridement and drainage, cervical esophagostomy, and feeding tube placement.²³

CARDIAC INJURY

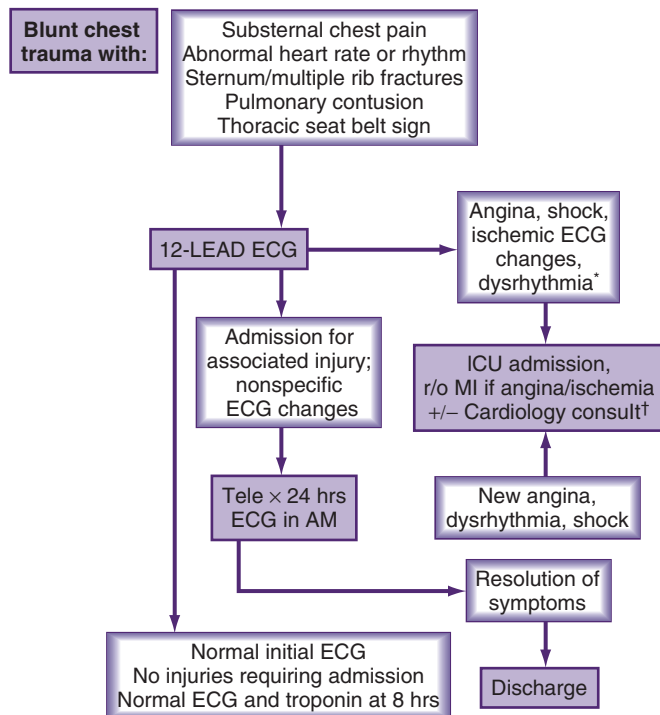

Blunt Cardiac Injury

Blunt cardiac injury (BCI) represents a wide spectrum of cardiac injuries, ranging from occult and inconsequential to lethal dysrhythmias, pump failure, or cardiac rupture. It can occur following virtually any trauma to the chest.

Diagnosis, Monitoring, and Treatment

The diagnostic criteria for BCI are not standardized; no test is 100% predictive of the uncommon but life-threatening complications of ventricular dysrhythmias and cardiac pump failure—the so-called significant BCI. The pivotal issue is to identify patients at risk and have them in a setting where the complication can be identified and treated promptly.

A guideline for monitoring patients with suspected BCI is depicted in Figure 169-2. The initial evaluation should include an ECG. Patients with shock, ischemic changes on the ECG, or significant dysrhythmias are admitted to the ICU. If angina or ischemic ECG changes are noted,

*Ischemic changes: ST elevation/depression, T wave inversion in ≥ 2 leads; Dysrhythmia: Frequent premature atrial/ventricular contractions, heart block, new atrial fibrillation/bundle branch block
 †Echocardiogram may be indicated in selected patients with unexplained or refractory shock, new murmur, or clinical suspicion of pericardial effusion/tamponade

FIGURE 169-2 ■ Evaluation for suspected blunt cardiac injury: blunt chest trauma with substernal chest pain, abnormal heart rate or rhythm, sternum or multiple rib fractures, pulmonary contusion, thoracic seat-belt sign. Ischemic changes consist of ST elevation or depression or T-wave inversion in two leads. Dysrhythmia consists of frequent premature atrial or ventricular contractions, heart block, new atrial fibrillation, or bundle branch block. Echocardiogram may be indicated in selected patients with unexplained or refractory shock, new murmur, or clinical suspicion of pericardial effusion or tamponade. ECG, electrocardiogram; MI, myocardial infarction.

the diagnosis of acute coronary syndrome should be pursued. Patients with significant blunt chest trauma and nonspecific ECG findings (e.g., sinus tachycardia) who are being admitted for associated injuries should have cardiac monitoring for 24 hours.²⁴ A subset of patients may not require admission for other injuries. These patients can be safely discharged from the ED if ECG normalizes and if a troponin-I level at 8 hours is less than 1.5 ng/mL.²⁵

Dysrhythmias are treated by pharmacologic suppression. The management of cardiogenic shock from cardiac pump failure may include early placement of a pulmonary artery catheter to optimize fluid administration and inotropic support. An echocardiogram may be indicated to exclude septal or free wall rupture, valvular disruption, or pericardial tamponade. Patients with refractory cardiogenic shock may require placement of an intraaortic balloon pump to decrease myocardial work and enhance coronary perfusion.

Comotio cordis is a distinct entity in which “virtually instantaneous cardiac arrest is produced by nonpenetrating chest blows in the absence of heart disease or identifiable morphologic injury to the chest wall or heart.”²⁶ In a series of 70 cases, Maron and colleagues reported a 90% mortality rate in a young (mean age 12 years) population of

patients.²⁵ An experimental model demonstrated that ventricular fibrillation is reproducibly triggered by a precisely timed blow during a narrow window within the repolarization phase of the cardiac cycle (15-30 msec before the peak of the T wave). Heart block may be produced by a blow during the QRS complex.²⁷

Pericardial Injury

Pericardial tears may result from direct thoracic impact or from an acute increase in intraabdominal pressure. Herniation of the heart through a large tear may be associated with significant cardiac dysfunction. A pericardial rub may be detected on physical examination. The CXR may demonstrate pneumopericardium, displacement of the heart, or bowel gas in the chest. Echocardiography or CT may be required to confirm the injury. In a stable patient, a subxiphoid pericardial window should be performed, followed by sternotomy in the presence of large hemopericardium or a visible pericardial tear. An unstable patient may require RT. Pericardial lacerations should be repaired, but large holes that cannot be closed primarily should be left widely open to prevent future cardiac herniation. A late complication is the postpericardiotomy syndrome, manifested by fever, chest pain, pericardial effusion, a pericardial rub, and ECG abnormalities; this is adequately treated with antiinflammatory agents.

Valvular Injury

Valve injuries are rare. Even in lethal cardiac trauma, the valves are injured in approximately 5% of patients. The most commonly injured valve is the aortic, followed by the mitral, tricuspid, and pulmonary. Aortic valve disruption may result in acute severe cardiac failure, but a mild injury may present with syncope or anginal symptoms. Mitral valve leaflet tears, or more commonly, rupture of papillary muscles or chordae tendineae, may also result in acute heart failure. A heart murmur will generally be present, and echocardiography and/or cardiac catheterization are used to confirm the diagnosis. Most valve injuries are amenable to supportive care until other injuries have been stabilized. Valve repair is generally preferred over valve replacement when feasible.²⁸

Septal Injury

Septal injuries are found in 5% to 7% of patients dying from blunt trauma. Ventricular septal ruptures are much more common than atrial septal injuries; they usually occur in the muscular portion near the apex. Characteristic physical findings include a systolic thrill and a harsh holosystolic murmur heard best at the left sternal edge and radiating to the right, but the symptoms may be delayed for hours or days as the defect enlarges. Atrioventricular conduction abnormalities may also be present, simulating myocardial ischemia, and severe hypoxemia may result from an acute left-to-right shunt. Prompt echocardiography is indicated to establish the diagnosis; cardiac catheterization may be needed.

Small septal defects may heal primarily, allowing expectant management with periodic follow-up. Surgical repair—either primary or with a patch graft—is indicated if the patient is hemodynamically compromised or has a left-to-right shunt with a shunt ratio of 2:1 or greater. Repair of the defect is delayed for several weeks if possible.²⁹

Coronary Artery Injury

Direct injuries to coronary arteries are rare. The left anterior descending artery is the most susceptible (76% of cases), followed by the right coronary artery (12%) and the circumflex coronary artery (6%). Surgical revascularization or repair of delayed complications related to infarction, such as ventricular pseudoaneurysms, may be indicated.

Penetrating Cardiac Injury

Cardiac penetration is rapidly lethal in 90% of gunshot wounds and up to 50% of stab wounds. All patients in shock with penetrating chest injuries between the right midclavicular line and left anterior axillary line, as well as the posterior left chest, should be considered to have a cardiac injury until proven otherwise.³⁰ The right ventricle, with its maximal anterior exposure, is at greatest risk, followed by the left ventricle, right atrium, and left atrium. Multiple cardiac structures are involved in a third of patients. Stab wounds are more commonly associated with tamponade, while gunshot wounds often result in exsanguination through a large pericardial defect.

Repair of cardiac injuries can be accomplished through either a median sternotomy or anterolateral thoracotomy incision. In a hemodynamically compromised patient, left anterior thoracotomy with transsternal extension is used for definitive repair. In a hemodynamically stable patient, sternotomy is generally preferred. A limitation of sternotomy is access to posterior mediastinal injuries. Satinsky clamps are useful in isolating atrial or caval injuries, whereas small ventricular lacerations are controlled digitally. Larger wounds may be stapled. Wounds that are very large are occasionally reparable using temporary caval inflow occlusion.³¹

Pericardial Tamponade

Potential pericardial tamponade should be suspected in all patients sustaining penetrating injuries to the anterior chest wall. Pericardial tamponade can be a two-edged sword: although it may limit initial blood loss, it can prove fatal by restricting diastolic filling of the heart.³² Because the pericardium is not acutely distensible, as blood accumulates the pressure in the pericardial sac rises to match that of the injured chamber. When the pressure approaches that of the right atrium, right atrial filling is impaired, and right ventricular preload is reduced; ultimately, this leads to decreased right ventricular output. Increased intrapericardial pressure also impedes myocardial blood flow, which leads to subendocardial and later subepicardial ischemia, with a further reduction of cardiac output. This vicious cycle may progress insidiously with injury to low-pressure conduits, or it may occur precipitously with a ventricular wound. Acute tamponade of as little as 100 mL of blood within the pericardial sac can produce life-threatening hemodynamic compromise.

Early diagnosis is key, as the ultimate cardiovascular collapse can be abrupt. Compensatory responses including tachycardia and vasoconstriction can transiently stabilize the hemodynamic status of the patient. Similarly, vigorous fluid administration may improve the patient's vital signs. The classic findings of Beck's triad (hypotension, distended neck veins, and muffled heart sounds) are present in less than 10% of patients; furthermore, Kussmaul's sign (neck vein swelling with inspiration) and pulsus paradoxus (systolic blood pressure drop with inspiration) are not reliable indicators of acute tamponade. In fact, neck veins may not become distended until hypovolemia is corrected.

In the setting of suspected pericardial tamponade, ultrasonography using subxiphoid and parasternal views (or formal echocardiography if immediately available) is extremely helpful if the findings are positive, although a negative ultrasonographic examination may be misleading if there is a pericardial laceration.³³ If pericardial fluid is demonstrated, the patient should be transported immediately to the OR for sternotomy. However, if ultrasonography is equivocal, a central venous pressure line should be inserted promptly. Persistently elevated central venous pressure in a patient with thoracic trauma should prompt consideration of subxiphoid pericardial window. If the pericardial ultrasonography is positive and there will be any delay in getting to the OR, pericardiocentesis should be done if there is any suggestion of cardiac compromise, because subclinical endocardial ischemia can lead to recalcitrant lethal dysrhythmias. The pericardial tap should be performed with a pigtail catheter to allow repeated aspiration during preparation for thoracotomy. In the setting of shock, evacuation of as

little as 15 mL of blood may dramatically improve the patient's hemodynamic profile. Pericardiocentesis is successful in decompressing tamponade in approximately 80% of cases; most failures are due to clotted blood within the pericardium. If pericardiocentesis is unsuccessful and the patient remains severely hypotensive (systolic blood pressure < 70 mm Hg), RT should be performed.

TRANSMEDIASTINAL PENETRATING TRAUMA

Transmediastinal trajectory of a bullet should be considered in the setting of (1) entry and exit wounds on opposite sides of the thorax, (2) a single entry wound with the bullet ending up on the opposite side of the thoracic cavity or in close proximity to the mediastinum, or (3) multiple gunshot wounds to the thorax. Significant injury, especially to the heart or great vessels, often results in prehospital death or hemodynamic instability. There is little controversy regarding the management of unstable patients: they should have emergent thoracotomy. However, stable patients may harbor occult injuries to critical mediastinal structures (heart, great vessels, trachea, or esophagus). Helical CT angiography (CTA) of the chest has proved useful in demonstrating the trajectory of missiles in the thorax.³⁴ In the setting of a potential transmediastinal gunshot wound, a CT scan may confirm a trajectory remote from the mediastinum, obviating further testing. A proven transmediastinal trajectory mandates further evaluation, tailored to the specific structures at risk. Our current approach to evaluating these patients is outlined in Figure 169-3.

THORACIC GREAT VESSEL INJURY

Patients with penetrating injuries to extrapericardial thoracic great vessels usually succumb in the field; however, an occasional patient arrives with a contained hematoma. Early CXR is critical to identify hemothorax, as well as a widened mediastinum or apical capping. Patients who are hemodynamically unstable should be taken directly to the OR; those in extremis should undergo RT. A reasonable approach can be inferred from the CXR and the location of the wounds. If the patient has a left hemothorax, a left anterolateral thoracotomy in the third or fourth intercostal space should be performed. Patients with a right hemothorax should likewise be approached via a right anterolateral thoracotomy. Unstable patients with injuries near the sternal notch may have large mediastinal hematomas or may have lost blood externally. These patients should be explored via a median sternotomy with cervical extension. Hemorrhage should be controlled digitally until the vascular injury is delineated. In a hemodynamically stable patient, CTA can facilitate a more directed approach. In the setting of pericardial trajectory, it must be remembered that collateral flow around the shoulder girdle can result in palpable pulses, even in the presence of a significant subclavian artery injury.

A median sternotomy, with appropriate extension, is used for exposure of the aortic arch branch vessels. In patients who have undergone RT, the left anterolateral thoracotomy incision may have to be extended to a bilateral anterolateral thoracotomy ("clamshell"). In exposing the proximal left subclavian artery, it may be necessary to create a full-thickness flap of the upper chest wall. This is accomplished with a partial sternotomy and supraclavicular extension. If necessary, the ribs can be transected laterally, allowing the flap to be folded laterally, but this is rarely required. This incision has been referred to as an *open-book* or *trapdoor thoracotomy*. The midportion of the subclavian artery is accessible via a supraclavicular skin incision.

The great vessels are rather fragile and can be easily torn during dissection or crushed with a clamp. For this reason, injuries adjacent to the aortic arch are oversewn, and a graft is inserted onto a new location on the arch. The graft is then sewn (without tension) to the distal artery. Nonoperative management of nonocclusive peripheral arterial injuries has proved successful, and there are limited data supporting similar management within the thorax for certain patients. Similarly, lesions associated with severe neurologic injuries are usually managed

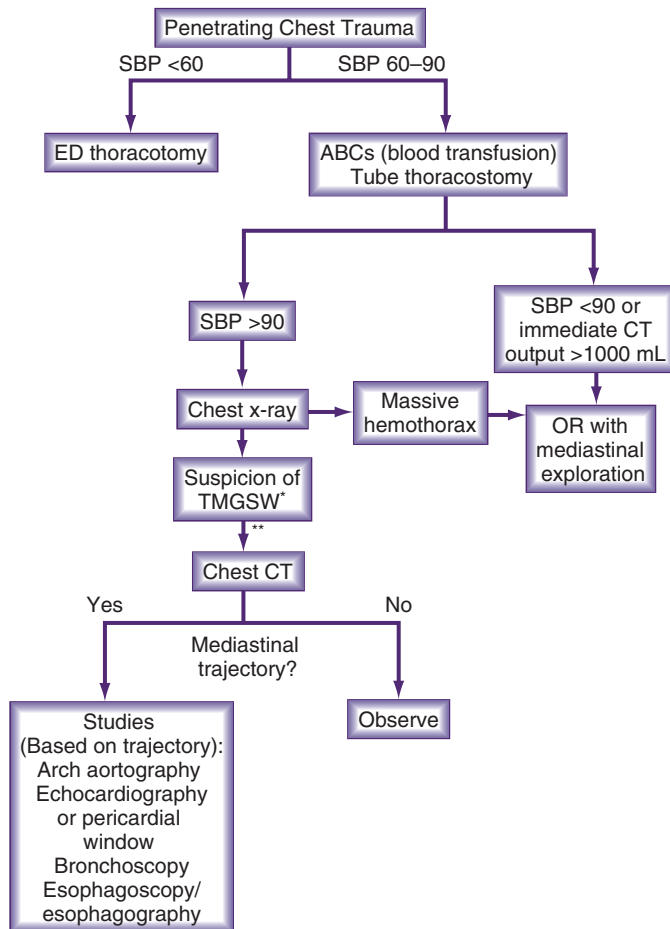

FIGURE 169-3 ■ Evaluation of suspected transmediastinal gunshot wounds (TMGSWs). ABCs, airway, breathing, circulation; CT, computed tomography; ED, emergency department; OR, operating room; SBP, systolic blood pressure.

*Suspect transmediastinal trajectory in the presence of entry and exit wounds on opposite sides of the thorax, a single entry wound with the bullet located in the contralateral hemithorax or adjacent to the mediastinum, or multiple gunshot wounds to the thorax.

**If there is evidence of mediastinal injury (pneumomediastinum, widened mediastinum on chest x-ray), consider proceeding directly to invasive diagnostic testing.

nonoperatively. Experience with intravascular stenting is growing, although long-term outcomes have not been reported.³⁵ Clearly unstable patients require operative control and repair; however, it appears that stent graft treatment of subclavian artery injuries is preferred in stable patients.³⁶

Blunt Thoracic Aortic Injury

Perhaps the most feared occult injury in trauma surgery is a blunt thoracic aortic injury (BTAI). The mechanism of aortic tears is believed to be primarily a shearing force. The tear usually occurs just distal to the left subclavian artery where the aorta is tethered by the ligamentum arteriosum. In 5% of cases, the tear occurs in the ascending aorta, in the transverse arch, or at the diaphragm. An estimated 85% of thoracic aortic injuries are fatal at the injury scene. A multicenter report from the American Association for the Surgery of Trauma (AAST) analyzed 274 accident-scene survivors of BTAI.³⁷ Motor vehicle crashes accounted for 81% of the injuries, with frontal impact in 72%, lateral

impact in 24%, and rear impact in 4%. Two additional series also documented substantial numbers of BTAI following lateral-impact crashes: 57 of 165 (35%) autopsy cases reported by Burkhart et al.³⁸ and 48 of 97 (50%) cases reviewed by Katyal et al.³⁹ Thus the surgeon should suspect this injury whenever there is significant energy transfer, regardless of directionality.

Chest x-ray is considered the initial screening tool of choice for determining whether further investigation is needed for BTAI. Commonly associated radiographic findings include mediastinal widening, obscured aortic knob, deviation of the left mainstem bronchus (downward) or nasogastric tube (rightward), and opacification of the aortopulmonary window (Fig. 169-4, A). In the AAST multicenter study,³⁷ widening of the mediastinum on the anteroposterior chest radiograph was present in 85% of cases. However, 7% of patients with torn aortas had normal chest radiographs. Dyer and colleagues⁴⁰ reported normal initial radiographs in 13% of patients. Thus, additional investigations are warranted in the setting of significant energy transfer. Thoracic aortography was previously considered the gold standard for diagnosis (see Fig. 169-4, B). However, helical CT scan is now well accepted as an excellent screening test (see Fig. 169-4, C).⁴⁰⁻⁴² When hematoma adjacent to the thoracic aorta is considered a positive finding, the sensitivity of CT for aortic injury is 100%.

There are currently a number of areas of controversy in the management of BTAI: immediate versus delayed repair, management of minimal aortic injuries (MAI), and open versus endovascular repair.

Immediate Versus Delayed Repair

Until the 1990s, BTAI was thought to require urgent repair to avoid early rupture. Recognizing significant morbidity and mortality in patients with severe associated injuries and comorbid medical conditions, the concept of immediate repair was challenged. The administration of beta-blockade to decrease systolic blood pressure (<100 mm Hg) and heart rate (<100 bpm), and therefore reduce aortic shear pressure, allowed the optimization of associated injuries and stabilization of target systolic blood pressure and heart rate.⁴¹ Numerous studies have established the safety of this approach. In fact, a recent AAST prospective multicenter trial found that delayed repair is associated with significant survival benefit.⁴³ Although patients with major associated injuries are most likely to benefit, the study supported delayed repair in all patients, irrespective of risk factors. A current practice guideline by the Eastern Association for the Surgery of Trauma (EAST) recommends delayed repair to reduce mortality and paraplegia.⁴²

Management of Minimal Aortic Injury

With increasing sensitivity of CT scans (as discussed with regard to pneumomediastinum), more MAIs are being diagnosed. These are defined as small (<1 cm) intimal lesions with minimal to no periaortic hematoma.⁴⁴ Fabian and colleagues⁴¹ identified MAI in 10% of BTAI and found that half of these lesions were missed on arteriography. Although the name suggests benign behavior, the Memphis group reported that 50% of MAIs had progressed to pseudoaneurysm formation by 8 weeks post injury.⁴⁴ MAIs are generally treated with beta-blockade and CT surveillance.⁴⁵

Open Versus Endovascular Repair

Over the past several years, open repair has been largely supplanted by thoracic endovascular aortic repair (TEVAR).⁴⁶ The weight of current evidence supports TEVAR as first-line therapy, given superior outcomes in terms of mortality, blood loss, and paraplegia.^{42,47} While long-term outcome data are still relatively sparse, they remain good, and improvements in devices will likely continue that trend.

In those patients who require open repair, a primary concern has been the occurrence of paraplegia from ischemic injury of the spinal cord. In the AAST study,³⁷ the paraplegia incidence was 1.6% in patients with cross-clamp times less than 30 minutes, but 12% if the time was greater than 30 minutes. A 20-year meta-analysis found a 19% incidence of paraplegia associated with this method and noted that average cross-clamp times were over 40 minutes.⁴⁸ The alternative

FIGURE 169-4 ■ Images from patient with descending thoracic aortic injury. **A**, Anteroposterior chest radiograph. Note widened mediastinum and widened left paratracheal stripe, indistinct aortic knob, and slight depression of left mainstem bronchus. **B**, Helical computed tomography (CT) scan of chest. Note periaortic hematoma (arrow). **C**, Digital subtraction arteriogram of aortic arch. Note pseudoaneurysm in the common location, distal to left subclavian artery (arrow).

approach is to provide some method for maintaining spinal perfusion during cross-clamping. The current preferred method is to use either active partial left heart bypass (siphoning blood from the left heart and pumping it to the distal aorta) or full bypass such as femoral-femoral bypass. The former can be a significant benefit in a patient with multiple injuries, particularly in those with intracranial hemorrhage.

However, occasional small cerebral infarcts have occurred, so heparin is administered unless contraindicated. The injury may be primarily repaired, or a graft may be inserted. A large multicenter trial suggested that polytetrafluoroethylene is the preferred graft material for aortic replacement, given its long-term patency and apparent resistance to infection.⁴⁹

KEY POINTS

Initial Assessment

1. Initial management of injured patients should follow the principles of the Advanced Trauma Life Support course.
2. Resuscitative thoracotomy will not yield productive survival when patients (1) sustain blunt trauma and require more than 10 min of prehospital CPR without response, (2) have penetrating wounds and undergo more than 15 min of prehospital CPR without response, or (3) manifest asystole without pericardial tamponade.

Pleural Space

1. Tube thoracostomy is not necessary for asymptomatic occult pneumothoraces.
2. Needle decompression should be done in the midaxillary line in the fifth intercostal space.

3. Prophylactic antibiotics do not reduce the incidence of chest tube-associated empyema or pneumonia and are associated with antimicrobial resistance.
4. Chest tube removal algorithms should include lung expansion, drainage less than 2 mL/kg/d, and a trial of 6- to 12-hour waterseal drainage.
5. High-volume chest tube output that abruptly decreases should raise the suspicion of clotted hemothorax.

Chest Wall Injury

1. Rib fractures in elderly patients are associated with significant morbidity and mortality.
2. Surgical stabilization of rib fractures should be considered for intractable pain or major chest wall deformity.

KEY POINTS—cont'd

Lung Injury

1. Treatment of pulmonary contusion is supportive, with mechanical ventilation used only when indicated.
2. Pulmonary tractotomy results in favorable morbidity and mortality rates compared with lung resection for trauma.

Tracheobronchial Injury

1. Bronchoscopy should be performed for cervical subcutaneous emphysema, pneumomediastinum, or pneumothorax with a persistent air leak.

Esophageal Injury

1. Contrast esophagography is the preferred diagnostic study, but videoendoscopy can be done at the bedside in intubated patients and is superior in the pharyngeal area.

Cardiac Injury

1. Blunt cardiac injury is commonly diagnosed, but cardiac enzymes, echocardiography, and nuclear medicine studies are not predictive of the uncommon but life-threatening complications of ventricular dysrhythmias and cardiac pump failure.
2. Echocardiography is most useful in identifying pericardial tamponade or intracardiac injuries.
3. All patients in shock who have penetrating chest injuries between the right midclavicular line and left anterior axillary line should be considered to have a cardiac injury until proved otherwise.

4. Ultrasonography and central venous pressure monitoring are critical adjuncts in diagnosing pericardial tamponade, as the classic findings of Beck's triad are present in very few patients.

Transmediastinal Penetrating Trauma

1. Helical CT scanning is useful in delineating the trajectory of potential transmediastinal gunshot wounds, allowing a truncated and cost-effective workup in stable, asymptomatic patients.

Thoracic Great Vessel Injury

1. A reasonable operative approach to unstable patients can be inferred from the chest radiograph and the location of wounds.
2. Blunt thoracic aortic injury should be suspected in any patient with severe energy transfer, regardless of mechanism.
3. Helical CT is an excellent screening test and should be considered even in the face of a normal chest radiograph if there is severe energy transfer.
4. Once aortic injury is diagnosed, the systolic blood pressure and heart rate should be controlled with a rapidly reversible beta-blocking agent.
5. TEVAR is the preferred approach for aortic repair.
6. During aortic repair, it is safest to provide distal circulation via a bypass circuit.
7. Delayed intervention is superior to immediate repair.

The acutely injured patient requires a rapid, systematic, and thorough evaluation guided by the Advanced Trauma Life Support principles.¹ A high suspicion for intraabdominal pathology must also be had as delays in diagnosis and treatment increase morbidity and mortality.² When evisceration or peritonitis are absent, history and physical examination findings that suggest intraabdominal injury are often subtle.³ This chapter will focus on the diagnosis, evaluation, and management of traumatic injuries (both blunt and penetrating) to the abdominal cavity. The principles of damage control surgery and the open abdomen will also be discussed.

■ BLUNT ABDOMINAL INJURY

Operative management is the primary therapy in patients with blunt abdominal injury who present with peritonitis or hemodynamic instability, accompanied by signs of abdominal trauma or hemoperitoneum. With its bedside availability and noninvasiveness, focused abdominal sonography for trauma (FAST) should be employed in all severely injured blunt trauma patients.⁴ FAST cannot be used to detect diaphragm, hollow viscus, or retroperitoneal injuries.⁵ Diagnostic peritoneal lavage (DPL) is useful for further evaluation of the abdomen in unstable patients with a negative FAST or in patients who require an emergency operation for an injury remote from the abdomen.⁶ DPL lacks sensitivity for retroperitoneal and diaphragm injuries.

For patients who do not require an immediate laparotomy, and who are hemodynamically stable, computed tomography (CT) is the standard diagnostic tool.⁷ While it is accurate in the diagnosis of solid organ injury, it lacks sensitivity and specificity for pancreatic, hollow viscus, and diaphragm injuries.⁸

■ PENETRATING ABDOMINAL INJURY

A penetrating abdominal injury from the nipple line anteriorly or scapular tip posteriorly to the buttocks inferiorly can produce both a thoracic and abdominal injury. After a rapid primary survey, the entire body must be inspected for penetrating wounds. Radiographs are taken to identify all foreign objects and to anticipate possible structures at risk. FAST is less useful in the evaluation of penetrating abdominal trauma except for the ability to detect hemopericardium.

Indications for immediate exploration of abdominal penetrating injuries include hypotension, peritonitis, and evisceration. In the absence of these signs in a stable patient with a reliable physical exam, serial abdominal examination may be an option.⁹ The need for exploratory laparotomy is then based on a change in abdominal examination, vital signs (especially temperature or heart rate), or white blood cell count.¹⁰

■ HEPATIC TRAUMA

The liver is the most commonly injured organ in patients suffering blunt abdominal trauma.¹¹ For hemodynamically stable patients, CT is the diagnostic test of choice as it provides rapid grading of the injury and detection of active hemorrhage.¹²

The majority (80%-85%) of blunt hepatic injuries are low grade (grade 1-3), with only 15% being high-grade injuries (grade 4-5).

Patients requiring immediate laparotomy for hemodynamic instability generally have grade 4 or 5 liver injuries. Approximately 70%-80% of liver injuries can be safely managed nonoperatively.^{13,14} Predictors of failed nonoperative management (NOM) of high-grade liver injury include age, male gender, higher Injury Severity Score (ISS), lower Glasgow Coma Scale, and hypotension.¹⁵

Successful NOM requires appropriate patient selection, high-quality CT, and the availability of an effective multidisciplinary team of intensive care physicians, experienced surgeons, and interventional radiologists.¹⁶ For most liver injuries requiring surgery, the indication is related to the development of a complication, such as abscess or bile peritonitis, rather than bleeding.¹⁷ For patients who do have evidence of ongoing bleeding from the liver injury, depending on the patient's hemodynamic status, magnitude of the liver injury, and associated intraabdominal injuries, either angiography or surgery is warranted.

Angiography/embolization enhances the success of NOM but should only be utilized in patients who are hemodynamically stable without other indications for operative intervention.¹⁸ Active extravasation of contrast on CT predicts the need for embolization.¹⁹ Complications of angioembolization include hepatic necrosis, gallbladder necrosis, bile leak, and abscess formation.²⁰

While NOM has resulted in lower mortality rates, complications of NOM of hepatic injury include bleeding, bile leak, hepatic necrosis, gallbladder necrosis, abscess, fistula, and thrombosis or pseudoaneurysm of the hepatic vasculature.^{17,21} Treatment of complications after NOM may include observation of small bilomas, endoscopic retrograde cholangiopancreatography (ERCP) and stenting of large bile leaks, percutaneous drainage of bilomas or abscesses, or surgery.²² Delayed bleeding is an uncommon complication.

Although NOM of liver injury offers benefits of low mortality, reduced transfusion requirements, and reduced length of hospital stay, up to 35% of patients with complex liver injuries will require early operation.^{17,22} Postoperative hepatic angiography may also be useful.¹⁹ Definitive management of liver injuries involves not only control of bleeding but also removal of devitalized or necrotic liver, control of bile leaks, and drainage.

■ PANCREATIC TRAUMA

Pancreatic injuries are relatively uncommon due to its well-protected position in the retroperitoneum, occurring in 0.2% to 2% of all trauma.²³ Blunt pancreatic injury is often due to a crushing force compressing the pancreas against the vertebral column, with injury to the pancreatic neck.

The Western Trauma Association and the Eastern Association for the Surgery of Trauma have published guidelines for pancreatic trauma diagnosis and/or management.^{24,25} Early diagnosis remains a challenge. Signs and symptoms of pancreatic injury may be subtle and become apparent only later in the postinjury course as pancreatic secretions become activated and pancreatic and peripancreatic inflammation increases. Initial physical examination, DPL, and ultrasonography are relatively insensitive in detection of pancreatic injury.²⁶

CT is the primary imaging modality used in the diagnosis of blunt pancreatic injury despite being an imperfect test, especially for early diagnosis and detection of pancreatic ductal injury.²⁷ The sensitivity of CT scans may improve with time after injury; therefore, a repeat CT

may be warranted for patients with persistent signs or symptoms consistent with pancreatic injury.

ERCP is the most sensitive technique, short of operative exploration, for diagnosis of pancreatic ductal injury.²⁸ ERCP can define ductal anatomy in patients presenting late after injury with complications such as persistent pancreatic fistula or pseudocyst.²⁹

The use of magnetic resonance cholangiopancreatography (MRCP) is limited by a variety of factors including patient status, associated injuries, and availability of magnetic resonance imaging (MRI).³⁰ In addition, MRCP does not offer the opportunity for therapeutic intervention.

The status of the pancreatic duct, the location of injury (proximal versus distal), and the overall status of the patient determine the most appropriate management. Pancreatic injury without evidence of ductal injury (grades 1 and 2) can be managed with débridement and external drainage alone. Distal pancreatectomy and drainage should be the treatment for most distal pancreatic injuries with ductal injury (grade 3).²⁴

Proximal pancreatic ductal injuries and disruption of the pancreatic head (grade 4 and 5 injuries) are difficult to manage. Recommendations range from simple drainage alone to complex procedures such as pancreaticoduodenectomy or on-lay pancreaticojejunostomy. Pancreaticoduodenectomy should rarely be required.

Mortality from pancreatic injury ranges from 9% to 34%.²⁴ Early mortality following pancreatic trauma is due primarily to associated injuries, predominantly vascular injuries. Sepsis, multisystem organ failure, and respiratory failure account for the majority of late deaths.³¹ Unlike mortality, which is dependent predominantly on the presence of associated injuries, the pancreatic injury itself becomes a major factor in late morbidity. The presence of main pancreatic ductal injury is associated with increased morbidity. Furthermore, the incidence of pancreas-related complications correlates with the grade of injury. Pancreas-related complications include pancreatic fistula, abscess, pseudocyst, pancreatitis, and hemorrhage due to erosion of adjacent retroperitoneal vessels. This erosion is itself secondary to the presence of activated pancreatic secretions or the presence of a pancreatic abscess.^{24,32}

■ SPLENIC TRAUMA

Most splenic injuries are managed nonoperatively, with the primary indication for surgery being hemodynamic instability.^{33,34} Splenic injuries are primarily assessed through contrast-enhanced abdominal CT, which allows determination of the injury grade, as well as identification of vascular abnormalities such as contrast blush or extravasation, pseudoaneurysm, or arteriovenous fistula.

Findings that correlate with failure of NOM include high-grade injuries (grade 4 or 5), high ISS, presence of pseudoaneurysms, arteriovenous fistulae, or active extravasation.^{35,36} Most patients (90%) who fail NOM do so within the first 3 days following injury, with 60% failing within the first 24 hours.^{35,37}

Angiographic embolization is an adjunct in the management of some splenic injuries with contrast extravasation on CT. However, this strategy should not be chosen in the unstable patient or in the patient with other indications for laparotomy.^{34,38-41} Complications of angiographic embolization include femoral access issues, pleural effusions, contrast-induced acute kidney injury, splenic infarction, abscesses, or cysts; splenic-specific complications occur more frequently with distal embolization.⁴²

■ UROLOGIC TRAUMA

Hematuria is the hallmark sign of genitourinary injury. Gross hematuria mandates further evaluation. Microscopic hematuria is further evaluated in the blunt trauma patient with hypotension, lower rib fractures, flank ecchymosis or tenderness, spine fractures, or high ISS.^{43,44} Renal injuries are seen in 1% to 5% of all trauma patients, with the vast majority (approximately 90%) resulting from blunt

mechanisms.⁴⁵ Given the well-protected location of the kidneys, major force is required for significant renal injury to occur.⁴⁶

Imaging to evaluate renal trauma is usually performed with CT, which allows staging, identification of preexisting renal pathology, and documentation of the presence of an uninjured kidney.⁴⁷ A substantial injury seen on the arteriovenous phase should prompt obtaining delayed images to evaluate for urine collections, or contrast extravasation consistent with injury to the collecting system.⁴⁸

The grade of injury predicts morbidity and mortality as well as the need for interventions, with higher grade injuries more likely requiring operations, ureteral stents, or interventional angiography with embolization or vascular stenting.⁴³ NOM has become the standard in most cases of blunt renal trauma, with the goals of renal salvage and avoidance of long-term complications.⁴⁹ Complications of NOM and partial nephrectomy include bleeding, urinoma, and infection.

In a study of over 15,000 blunt trauma patients, bladder ruptures were most commonly diagnosed on CT cystogram and were commonly associated with pelvic fractures (80%) and hollow viscus injury (35%).⁵⁰ A higher risk of death is seen with intraperitoneal bladder injuries with or without a concomitant extraperitoneal injury, compared with only extraperitoneal injuries.⁵¹ A follow-up cystogram is recommended before catheter removal after complex repairs to the trigone or those requiring ureteral reimplantation. However, cystograms are not required for simple injuries.⁵²

Ureteral injuries are uncommon and occur more in penetrating than in blunt trauma.⁵³ The most commonly associated injury with blunt ureteral trauma is pelvic bone fracture, whereas penetrating ureteral trauma patients sustain more hollow viscus and vascular injuries.

A straddle injury or anterior pelvic rami fracture may be associated with a urethral injury, particularly in males. Signs of urethral injury include blood at the meatus, inability to void, perineal hematoma, or high-riding prostate gland. A retrograde urethrogram should be obtained prior to placement of a bladder catheter in these patients.

■ HOLLOW VISCUS INJURY

Hollow viscus injury (HVI) is commonly the result of penetrating abdominal injury. These injuries are generally found during routine exploration of the abdomen. Bowel injury from blunt trauma is relatively uncommon, difficult to diagnose, and carries with it a higher morbidity in the setting of delayed intervention.^{8,54,55} Moderate to large amounts of free fluid on CT after blunt abdominal trauma without evidence of solid organ injury, should raise the suspicion of an HVI and the need for exploration.^{56,57} Intestinal injury may be present despite normal findings by CT.⁵⁵ While CT may detect free air, the presence of free fluid, seatbelt sign, or radiographic signs of bowel trauma are highly predictive of injury.⁵⁸ The presence of blunt splenic and/or hepatic injuries predict a higher incidence of HVI, especially if combined.⁵⁹ Treatment of HVI requires exploration.

■ DIAPHRAGMATIC TRAUMA

Blunt diaphragmatic injury is important yet challenging to diagnose. The chest radiograph is diagnostic in 25% of cases, abnormal but not diagnostic in 50% of cases (blunting of the diaphragm, presence of haziness or infiltrates at the lung base), and normal (even in retrospect) in 25% of cases.⁶⁰ A second study evaluated the utility of CT scans. Upon retrospective review by a board-certified radiologist, only 57% of 42 patients who sustained blunt trauma and had preoperative CT scans of the torso had evidence of diaphragmatic injury on CT.⁶¹ Diaphragmatic injury is more common on the left side.⁶² Acute injury to the diaphragm is repaired through the abdomen rather than the chest because of the high likelihood of associated abdominal injury.

Diaphragmatic injuries from penetrating trauma are very difficult to diagnose, as the hole is generally small. Penetrating thoracoabdominal wounds, particularly on the left side, may result in hernias that entrap intestine years later. If the trajectory of a penetrating injury

suggests the possibility of a left-sided diaphragmatic injury, either laparoscopy or laparotomy is generally indicated.

DAMAGE CONTROL

Damage control refers to truncated surgical operations to control immediately life-threatening problems, followed by a period of vigorous ongoing resuscitation prior to subsequent return to the operating room for definitive repair of injuries.⁶³ Damage control surgery became widespread due to the recognition that prolonged efforts to completely correct anatomic abnormalities often resulted in technically adequate repairs but also resulted in patients who were physiologically exhausted and often died from irreversible shock, acidosis, hypothermia, and coagulopathy.⁶⁴

Damage control entails rapid control of hemorrhage and enteric contamination, a truncated operation, followed by temporary abdominal closure; all ideally performed in 1 hour or less.^{63,64} The patient is subsequently scheduled to return to the operating room within 24 to 48 hours, unless they require reoperation sooner due to ongoing bleeding or source control. At reoperation, packs are removed or replaced, devitalized tissue is resected, vascular repairs are performed, bowel anastomoses or stoma are created, feeding tubes are placed, and the abdominal wall is formally or again temporarily closed. Postoperative resuscitation may include angioembolization, particularly for arterial bleeding from hepatic injuries or pelvic fractures.

Care of the patient following a damage control operation focuses on resuscitation and preparation for the expected return to the operating room. The goals are rewarming, reversal of coagulopathy, and restoration of adequate perfusion. A complete reassessment with a systematic physical examination and adjunctive radiologic studies, as indicated, is essential to avoid missed injuries. It may be possible to complete radiographic assessments of the spine or extremities prior to reoperation, but the risks of transporting critically injured patients to remote diagnostic suites must be weighed against the potential benefits of finding or excluding particular injuries. Trips outside of the intensive care unit should be minimized. Correct placement of all tubes and lines should be confirmed. Laboratory parameters including acid-base status,

oxygenation, hemoglobin concentration, and coagulation profile should be monitored closely and corrected expeditiously. The inability to correct these abnormalities often suggests the need to return to the operating room. The operating surgeon must convey key information about the expected postoperative course, including critical clinical parameters that must be recognized and reported. Changes in drain output, critical laboratory values, increasing transfusion requirements, and changes in wound appearance all indicate potential deterioration. Once the patient returns to a relatively normal physiologic state, then return to the operating room for definitive repairs is undertaken.

THE OPEN ABDOMEN

A consequence of damage control is an open abdomen that refers to the unapproximated abdominal wall fascia. Massive swelling and edema of the abdominal viscera following resuscitation can result in increased intraperitoneal pressure and resultant organ dysfunction, referred to as the *abdominal compartment syndrome*.⁶⁵ Leaving the abdomen open shortens the duration of the initial operation, simplifies reexploration, and prevents abdominal compartment syndrome by creating a protected but flexible space for the enlarged viscera. Management of the open abdomen is not straightforward and carries with it significant morbidity, including enterocutaneous or enteroatmospheric fistulas and giant ventral hernias.⁶⁶ Because of these complications, multiple strategies to close the abdominal wall fascia as soon as possible have been employed.⁶⁷ However, none of these techniques has been universally successful, and optimal management of the open abdomen remains an area of active research.

CONCLUSION

Appropriate management of patients who have sustained abdominal trauma requires astute clinicians who are part of a multidisciplinary team. Significant morbidity and mortality can result, particularly from delays in diagnosis or treatment. Coordination between the surgeon and the intensivist, in particular, is essential to assure patients the best outcomes possible.

Pelvic and long bone fractures have serious local and systemic consequences for the trauma victim. Familiarity with the sequelae of serious orthopedic injuries is essential if intensive care unit (ICU) management of these patients is to have a successful outcome. The evolution of a multidisciplinary approach using a directed clinical decision-making pathway can lead to improved patient survival, reducing early deaths from exsanguination and late deaths from shock and multiple organ failure.¹

■ PELVIC FRACTURE

Pelvic fractures are present in about 10% of patients presenting to a level I trauma center after blunt trauma.² Pelvic fractures represent approximately 3% of skeletal injuries evaluated in major trauma centers.³ The incidence of pelvic fractures is highest following a motor-cycle crash, pedestrian trauma caused by a motor vehicle, falls from heights greater than 15 feet, and motor vehicle crashes, in that order.² Overall mortality due to pelvic fractures ranges from 10% to 16%; the highest mortality (around 45%) is attributed to open pelvic fractures.^{3,4} The incidence of solid and hollow organ injury and other skeletal trauma is high in patients with pelvic fractures, owing to the powerful forces involved.^{2,5} More than 90% of these individuals have associated gastrointestinal (5%) and other abdominal injuries (16.5%).²

The transfusion requirement for patients with pelvic fractures and a mean Injury Severity Score (ISS) of 21.3 is eight units of packed red blood cells but can be much greater.⁶ Complete dissociation of the posterior pelvis has the highest degree of hemorrhage and associated mortality.^{7,8} Less than 1% of all patients with pelvic fractures have hypotension secondary to blood loss due to the fracture itself.^{6,9} Nevertheless, 12% of patients with open pelvic fractures die as a direct result of hemorrhage.¹⁰

Hemorrhage from unstable pelvic fractures can be minimized by early reapproximation and stabilization of the pelvic ring. If external pelvic fixation is unsuccessful at restoring hemodynamic stability, after initial resuscitation, angiography to evaluate and treat pelvic arterial bleeding is indicated. Pelvic arterial disruption is responsible for hemorrhage in less than 5% of all cases of pelvic fracture.^{8,11} A blush of contrast identified on pelvic computed tomography (CT) scan is evidence of arterial bleeding and is an indication for angiography. Predictors of positive angiography have been postulated to be the presence of sacroiliac joint (SIJ) disruption, female gender, and the duration of hypotension.¹¹ Early and aggressive angioembolization has been shown to improve outcomes in properly selected patients. An algorithmic team approach can provide significant benefit, helping to reduce blood loss and thereby improving the success of nonoperative management.¹² Recurrent pelvic bleeding has been found following angiography and embolization in 8% to 23% of patients.⁹ Intensive care surveillance is mandatory even after a stable response to resuscitation.

■ LONG BONE FRACTURE

The most studied and serious long bone fracture is a fracture of the femur. Approximately 15% of seriously injured motor vehicle passengers presenting to a level I trauma center have femur fractures.¹³ Some 8% to 10% of these patients have bilateral fractures.^{14,15} The mortality rate for a unilateral fracture of the femur is 10% to 12%.^{14,15} Mortality

increases to 26% to 33% with bilateral fractures and is increased by 20% in patients above the age of 65.¹⁴ The highest incidence of femur fractures in the trauma population occurs in young men, with midshaft fractures being the most common as a result of high-energy impact.¹¹ Patients with bilateral fractures have an increased incidence of head injury, requirement for laparotomy, and pelvic fractures compared to those with a unilateral femur fracture.^{14,15} As with pelvic fractures, death is more closely associated with the severity of associated injuries rather than the fracture itself.^{14,15} The American College of Surgery's Committee on Trauma continues to recommend that femur fractures in polytrauma patients be repaired within 12 hours, provided the patient is hemodynamically stable.¹⁶ In the patient who presents with a closed femoral fracture and associated hypotension, other sources of hemorrhage should be considered.

■ LOCAL COMPLICATIONS

Infection

Infection can manifest as an acute complication in the setting of both long bone and pelvic fractures with the potential for osteomyelitis. Diagnosis can be achieved using CT, magnetic resonance imaging (MRI), three-phase bone scan, or radiolabeled white blood cell scans. The most common causative organism is *Staphylococcus aureus*, but infection may also be due to *Pseudomonas aeruginosa* and Enterobacteriaceae.¹⁷ The best option in high-risk open fractures remains prophylactic antibiotics administered parenterally within 6 hours, typically consisting of a first-generation cephalosporin (Cefazolin) and an aminoglycoside (Tobramycin).

Gas gangrene or necrotizing fasciitis (*Clostridium perfringens*, *Streptococcus* sp., anaerobes, and coliform bacteria) can occur within the first 24 hours after fracture or operative repair. These fulminant, necrotizing infections usually occur in the setting of open fractures with extensive soft-tissue injury requiring débridement and are especially likely if there is a delay in treatment and/or with the presentation of shock. Tetanus prophylaxis consists of 0.5 mL of adsorbed toxoid promptly administered intramuscularly (IM) on presentation for all patients with traumatic wounds, including open fractures, who have not received a booster within the past 5 years.

Compartment Syndrome

Compartment syndrome (CS) is a potentially devastating complication that arises in the setting of either open or closed fractures. Tissue edema and bleeding raise the pressure in the fixed volume of a fascial compartment, which impedes blood flow, especially in arterioles and capillaries, resulting in tissue ischemia. Nervous tissue demonstrates functional abnormalities after 30 minutes of ischemia, with irreversible loss of function occurring after 12 to 24 hours. Muscle, on the other hand, does not exhibit functional defects for up to 2 to 4 hours, with irreversible loss of function only occurring after 4 to 12 hours. Capillary permeability also increases, resulting in further tissue edema.¹⁸

The most common location for compartment syndrome after lower extremity fracture is the anterior compartment of the leg. This complication usually results from closed tibia fractures. Up to 17% of patients with a tibia fracture secondary to a motor vehicle crash develop a

compartment syndrome.¹⁹ Compartment syndrome of the thigh can develop after open or closed fracture and may also develop after operative treatment of the fracture. Compartment syndrome of the arm, buttock, and foot are also possible after fracture. Risk factors associated with developing compartment syndrome include the severity of the fracture and associated soft tissue injury, the use of compression devices such as military antishock trousers or tourniquets, and systemic hypotension.^{18,20}

Diagnosis of compartment syndrome can be made on clinical grounds and is established when the compartment is tense on physical examination, severe pain is present with passive motion, the compartment is tender throughout, and sensory nervous function is impaired. Loss of distal pulses is often the last manifestation of compartment syndrome. The diagnosis must be made early before permanent tissue damage has occurred. Serial examinations are critical to monitor for compartment syndrome in patients at risk.¹⁸

Measurement of compartment pressure is an additional way to confirm the diagnosis; however, measurements are unnecessary when the diagnosis is evident on clinical grounds. Measurement of compartment pressure is useful when the physical examination is limited because the patient is unresponsive due to head injury or sedation. Compartment pressure values ranging from 30 to 45 mm Hg have been recommended as the threshold for triggering surgical intervention.¹⁹ Compartment pressures are measured by placement of a sterile needle connected to a pressure transducer into each compartment. Alternatively, commercial devices such as the Stryker compartment monitor (Stryker, Kalamazoo, MI) are available that accomplish the same task.

Treatment is by urgent, complete surgical fasciotomy to open all affected compartments. Fasciotomy can be performed in the ICU if the patient is too unstable to be transported to the operating room. Complete fasciotomy within 12 hours of onset results in a normal functional outcome in 68% of cases, whereas delay decreases the likelihood of successful outcome to 8%.²¹

In light of the fact that compartment syndrome can lead to irreversible neurologic and muscular damage, early diagnosis cannot rely solely on clinical findings. Hence, prophylactic fasciotomy has been advocated. Subsequent to this, a trend toward liberal use of "prophylactic fasciotomy" has been noted. According to Abouezzi et al. the most important factor influencing the need for fasciotomy is the location of the vascular injury. Popliteal vessel injuries are often associated with warm ischemia and prolonged repair time in the operating room.²² The overall incidence of neurologic damage due to a delayed, or lack of fasciotomy is difficult to determine.²²

Once the compartment has been opened, wash-out of the metabolic products of ischemia occurs. It is critical to closely monitor acid-base status, serum potassium and phosphate concentrations, serum creatinine kinase (CK) levels, fluid status, and renal function. Serum CK and creatinine measurements should be routinely done, with underlying concern for muscle injury or the development of renal failure. Serum myoglobin measurement is not necessary for the diagnosis and management of rhabdomyolysis. Since serum myoglobin is cleared more rapidly than CK, its utility is marginal, particularly when the diagnosis of rhabdomyolysis is delayed.²⁰ Urine myoglobin is not a sensitive or specific measurement for the development of acute kidney injury (AKI).

Rhabdomyolysis

Rhabdomyolysis can occur for several reasons after skeletal trauma. The disease and its pathophysiology were first described in 1941 during the "Blitz" of London. The severity of muscle necrosis depends on multiple factors including loss of arterial supply, increased compartment pressure secondary to prolonged or severe compression/injury, length of time without effective blood flow, and delayed resuscitation leading to hypovolemic shock.²³ A high index of suspicion must be maintained to facilitate early diagnosis. The most obvious cause is direct injury to muscles surrounding the fracture site. Direct injury to

skeletal muscle tissue is especially likely when the mechanism of injury results in the transfer of a great deal of energy. Second, rhabdomyolysis can occur following compression of tissues for a prolonged period after an injury. The compression causes ischemic injury to the involved muscle. Last, rhabdomyolysis can result from compartment syndrome due to a fracture. Again, the mechanism involves compression of circulation resulting in an ischemic injury. All three mechanisms of rhabdomyolysis can be exacerbated by hemorrhagic shock.²⁴

Successful treatment of rhabdomyolysis involves aggressive intravenous (IV) fluid therapy to maximize tubular flow rate, avoiding the accumulation of myoglobin in the renal tubules, and preventing the occurrence of hyperkalemia. Administration of iron-chelating agents such as desferrioxamine (standard dosage for rhabdomyolysis not established) and alkalization of urine using sodium bicarbonate as 50% of the resuscitation fluid (150 mEq dissolved in 1 L of 5% dextrose solution) or a carbonic anhydrase inhibitor such as acetazolamide are recommended by some experts. Ultimately, acute renal failure may necessitate hemofiltration or hemodialysis.^{25,26,27} In our institution, we aim to maintain a urine output greater than 1 to 2 mL/kg/h using IV fluids and follow serial serum CK and creatinine levels. We have had good success in avoiding acute renal failure without the use of urine alkalization or iron-chelating agents.

Fat Embolism Syndrome

Pathophysiology

Fat embolism syndrome occurs when marrow fat particles embolize from bone marrow to the pulmonary and systemic venous circulation via injured veins in the setting of acute fracture or fracture repair. Larger particles lodge in the pulmonary circulation, whereas smaller particles (7–10 μ m) will pass through to the systemic circulation. Estimates of the number of patients with fractures who develop pulmonary, cutaneous, and neurologic manifestations of fat embolism syndrome vary between 0.5% and 20%.^{17,28} It is estimated that 5000 deaths due to fat embolism syndrome occur annually after pathologic fractures, traumatic fractures, and orthopedic surgery.²⁹

Clinical Manifestations

Clinical diagnosis of fat embolism syndrome is based on the presence of the classic triad of respiratory compromise, mental status changes, and petechial rash in the setting of long bone fractures or orthopedic surgery involving long bone manipulation.³⁰ In patients with long bone fractures, 60% to 85% manifest symptoms within 24 to 48 hours. Therefore, in the appropriate setting, the rash is pathognomonic and presents in only 20% to 50% of cases.³¹

Severity can vary from subclinical, to subacute clinically apparent symptoms, to fulminant acute symptoms.³² The subacute course is associated with mild respiratory dysfunction and mild neurologic manifestations or cardiovascular compromise. The fulminant variety can involve any of the following: rapidly progressive acute respiratory distress syndrome (ARDS), complete cardiovascular collapse, or deep coma possibly resulting in death.³³

In trauma patients, it may be difficult to distinguish fat embolism syndrome from other causes of compromised pulmonary function. Indeed, the cause of respiratory compromise in multitrauma patients with significant long bone fractures can be multifactorial, including fat embolism syndrome, direct pulmonary/thoracic cavity trauma, and ischemia reperfusion injury with systemic activation of the inflammatory response.

The cardiovascular effects of fat embolism syndrome are mainly attributable to partial occlusion of pulmonary arterial flow resulting in acute pulmonary hypertension, and increased right ventricular afterload. These effects also vary in severity from sinus tachycardia, to reversible hypotension, to irreversible profound shock due to right heart failure resulting in death.^{17,35,29} Changes on the electrocardiogram include sinus tachycardia, bradycardia, other arrhythmias, and ST-segment changes.^{17,35,32} Treatment is supportive, with inotropic agents to increase contractility of the right ventricle so as to overcome

the adverse effects of increased afterload. Central nervous system manifestations of varying degrees are present in 70% to 80% of patients with fat embolism syndrome.³⁶ These findings can vary from mild confusion or restlessness to profound coma resulting in death.³³

Petechial rash is present in up to 50% of cases and is usually seen on the chest, neck, and axilla, although less often the rash appears on mucous membranes or the conjunctiva.^{37,28,32} Retinal changes can also be observed and include microinfarcts, cotton-wool spots, and flame-like hemorrhages.^{36,32} Petechial rash is usually a late sign of fat embolism syndrome.

Diagnosis

Many laboratory abnormalities are encountered in cases of fat embolism syndrome, but none is specific. Bronchoalveolar lavage has been advocated as a more specific test to diagnose fat embolism syndrome. Findings on chest CT scan include patchy ground-glass or nodular opacities and thickening of the interlobar septa. Because they most often occur 24 hours or more after injury, they can usually be differentiated from contusion, which should be evident earlier. CT findings in more severe cases of fat embolism syndrome include more extensive bilateral patchy airspace consolidation; similar abnormalities can also be seen on the chest radiograph.^{38,39}

Treatment

The mainstay of treatment for fat embolism syndrome is supportive. Pulmonary manifestations often respond to supplemental oxygen, but more severe cases of fat embolism syndrome develop into ARDS and multiple organ system failure, requiring prolonged mechanical ventilation. Cardiac dysfunction occurs due to increased pulmonary resistance, and shock due to fat embolism syndrome may require inotropic support.

The most important treatment of fat embolism syndrome is prevention. In the setting of traumatic fractures, prevention is achieved by providing early fixation. Multiple experimental and clinical studies clearly show that early fracture fixation (within 24 hours) decreases both the pulmonary and cardiac effects of fat embolism syndrome, as compared with delayed (>24 hours) fixation and nonoperative treatment.^{17,35,32,40-42} Intraoperative use of transesophageal echocardiography (TEE) can be a very sensitive monitor to detect fat emboli. The emboli appear as showering white flakes flowing or tumbling through the right atrium.⁴²

Thromboembolism

Pathophysiology

Venous injury, stasis, and hypercoagulability can all contribute to the risk of thromboembolism after pelvic or long bone fracture. Embolic thrombi to the pulmonary circulation or systemic circulation (paradoxical embolization) can originate in the deep veins of the thigh, pelvis, or upper extremity. Calf vein thrombosis, in general, does not embolize but extends to involve more proximal deep veins 20% to 25% of the time.

Risk Factors

A number of risk factors for thromboembolic disease including femur, tibia, and pelvic fractures, have been identified in trauma patients. Other identified risk factors include age greater than 40 years, immobility, blood transfusion, multiple trauma, head injury, spinal fracture, spinal cord injury, and high ISS.^{17,32,43-49} However, a systematic review of the literature by the Eastern Association for the Surgery of Trauma (EAST) found that only spinal fractures and spinal cord injuries were consistently shown to be associated with a higher risk of deep vein thrombosis (DVT).⁵⁰

Prophylaxis

Elevation of the affected extremity and passive motion exercises increase lower extremity venous flow rates and reduce DVT.¹⁷ Lower extremity sequential compression devices decrease the incidence of

DVT by up to 90% in orthopedic patients.¹⁷ Compression devices placed on the foot have also been shown to decrease the incidence of DVT in patients undergoing orthopedic surgery for elective indications, or trauma.¹⁷ These devices are useful when the anatomy of injury and surgery preclude placement of sequential compression devices on the leg.¹⁷ Similar improvements in the thromboembolism rate have been seen in the surgical ICU population.⁵¹ In the multitrauma population, some studies have shown sequential compression device use to be equivalent to the use of low-dose heparin, whereas other studies have shown no improvement in thromboembolic events when compared to no prophylaxis.⁴⁹ Despite conflicting data in the literature, the use of sequential compression devices continues to be a mainstay of thromboembolism prophylaxis in the skeletal trauma population because of its low cost, ease of use, and inherent safety. The salutary effects of sequential compression devices are thought to include improved venous flow, and activation of endogenous antithrombotic mechanisms. The anticoagulant effects of sequential compression devices decrease minutes after discontinuing the device, emphasizing the importance of continuous therapy.^{50,51} Because of its low cost, non-invasive nature, and high accuracy, color-flow duplex ultrasonography has become the test of choice for DVT.⁵² Aggressive screening and prophylaxis can reduce the incidence of asymptomatic venous thromboembolism (VTE) diagnosed by duplex ultrasonography.⁴⁵

Low-dose unfractionated heparin (5000 units IV, 2-3 times daily) decreases the incidence of thromboembolic events when compared with placebo in various populations of acutely ill patients. These studies have included orthopedic and nonorthopedic, critically ill and noncritically ill patients. Overall reductions in thromboembolic rates are of the order of two- to threefold.^{50,51} However, multiple studies of trauma and orthopedic patients, including two meta-analyses, have failed to show significant improvement in the rate of thromboembolic events when low-dose unfractionated heparin is compared to placebo.^{17,50}

The literature on low molecular weight heparin (LMWH) is more convincing. Several studies have shown that treatment with LMWH decreases the incidence of thromboembolism and has an excellent safety profile in patients with hip fracture or multisystem trauma.^{17,43} Moreover, studies have also shown that LMWH (enoxaparin, 30 mg subcutaneously [SQ] every 12 hours) provides superior VTE prophylaxis when compared to low-dose unfractionated heparin (5000 units SQ every 12 hours) in the trauma population.^{50,53}

Several studies have shown improved efficacy using combined sequential compression devices and low-dose unfractionated heparin or LMWH therapy when compared to either therapy alone in stroke, cardiac surgery, and neurosurgery populations.⁵² Other studies however, have shown no difference between combined and single-modality therapy.⁵¹ Further study of the fracture population is needed.

Treatment

Treatment of DVT and pulmonary embolism in patients with orthopedic injuries or multiple trauma involves a balance between the risk of bleeding and thromboembolic disease. Although virtually all pulmonary emboli arise from DVT in the thigh, pelvis, or upper extremity, calf vein thrombosis tends to propagate into the proximal veins, meaning that treatment should aim to avoid embolic phenomena.^{54,55} Treatment of DVT and pulmonary embolism usually starts with full anticoagulation using unfractionated heparin. Once therapeutic heparinization has been achieved for an average of 72 hours, treatment with sodium warfarin is begun. Patients are usually kept on bedrest for this period to prevent embolic events.^{55,56} Alternative therapy includes LMWH.

Inferior vena cava filters are generally reserved for patients who have failed anticoagulation, exhibit embolic phenomena or propagation of clots while on full anticoagulation, or are inappropriate candidates for systemic anticoagulation.^{51,57} Prophylactic use of inferior vena cava filters involves patients who have no documented pulmonary emboli or DVT but are thought to be high risk due to numerous other factors. The literature varies in attempting to ascertain what defines the "high-risk" patient. It is well recognized, however, that immobility,

venous stasis/injury, inflammatory or hypercoagulable states, and severely injured patients at risk of bleeding are contributory factors to the development of VTE and thromboprophylaxis failure.⁵⁸⁻⁶² Therefore, prophylactic use of inferior vena cava filters should be limited to those patients deemed high risk despite standard preventive measures (compression devices, anticoagulation).

Prognosis

More than 50% of deaths caused by pulmonary embolism occur within the first hour. After the first hour, patients are at a 2.5% to 10% risk of dying when treated adequately. Inadequate treatment carries a 30% risk of death.

KEY POINTS

1. Most deaths in patients with pelvic fracture are from head injury, nonpelvic hemorrhage, pulmonary injury, thromboembolic complications, and multiple organ system failure.
2. Hemorrhage from unstable pelvic fractures can be minimized by early reapproximation and stabilization of the pelvic ring. If this is unsuccessful, angioembolization can be helpful and potentially lifesaving. Angioembolization is most often used to decrease blood loss and improve success when attempting nonoperative management of hemorrhage, but it can also be used as an adjunct therapy before, during, and after an operating room (OR) visit. Direct preperitoneal pelvic packing has been suggested to help reduce transfusion requirements and the need for angiography.
3. Approximately 15% of seriously injured motor vehicle passengers presenting to a level I trauma center have femur fractures.
4. Associated injuries occur in more than 80% of patients and are responsible for more than 90% of deaths in patients with femur fracture.
5. Infection can manifest as an acute complication of open or closed fractures, with gas gangrene or necrotizing fasciitis being life-threatening infections. Treatment generally consists of débridement and antibiotic therapy.
6. Tetanus can result from any open fracture, but patients who have had farming accidents are at particularly high risk. Diagnosis relies on clinical recognition. Treatment consists of supportive care, surgical débridement, prompt passive immunization, and antibiotics.
7. Diagnosis of compartment syndrome can be made on clinical grounds when the compartment is tense on physical examination, severe pain is present with passive motion, the compartment is tender throughout, and sensory nervous function is impaired.
8. Treatment of rhabdomyolysis involves aggressive IV fluid therapy to avoid accumulation of myoglobin in the renal tubules and aid the prevention of hyperkalemia. Monitoring of urine output and serum CK and creatinine levels is mandatory.
9. An estimated 5000 deaths due to fat embolism syndrome occur annually after pathologic fracture, traumatic fracture, and orthopedic surgery combined.
10. Diagnosis of fat embolism syndrome is based on the presence of the classic triad of respiratory compromise, mental status changes, and petechial rash in the setting of long bone fractures or orthopedic surgery. Treatment is supportive, with lung protective strategies and aggressive fluid balance monitoring.
11. A number of risk factors for thromboembolic disease have been identified, including long bone and pelvic fractures, age greater than 40 years, immobility, blood transfusion, multiple trauma, head injury, spine fracture, spinal cord injury, and high ISS.
12. Signs and symptoms may be present in only 15% of patients diagnosed with DVT by venography.
13. Because of its low cost, noninvasive nature, and high accuracy, color-flow duplex ultrasonography has become the test of choice for DVT.
14. Treatment of DVT and pulmonary embolism usually starts with full anticoagulation using unfractionated heparin, transitioning to sodium warfarin or LMWH.
15. Fifty percent of deaths caused by pulmonary embolism occur within the first hour. After that, patients are at a 2.5% to 10% risk of dying when treated adequately and at a 30% risk of death when untreated.

Injury is a significant health burden in the pediatric population. It is defined as a sudden transfer of energy (thermal, electrical, mechanical, chemical, or radiation) that is physiologically intolerable or as damage that results in psychologic harm, deprivation, or maldevelopment.¹ Injuries are often classified as either intentional or unintentional. In the United States, injury remains the leading cause of mortality in children and remains a significant health burden. In 2011, more than 23 million children and young adults (age less than 24 years) were seen in an emergency department (ED) for injuries. The total cost of pediatric injury in the United States, including hospitalizations, ED visits, and permanent disability and death is estimated to be \$87 billion annually.² As children have unique anatomic and physiologic considerations, physicians caring for injured children must understand that this population is different from adult populations and that they require specialized treatment to reduce morbidity and improve survival. This chapter provides an overview of caring for critically injured pediatric patients.

TRAUMA SYSTEMS, CENTERS, AND TEAMS

The American College of Surgeons (ACS) Committee on Trauma first advocated inclusive trauma systems in 1991. This concept advocated that the trauma system be broadened to include all phases of injury and also include a multidisciplinary approach for the treatment of trauma. Trauma systems have now matured to include a network of verified trauma centers within most states and regions.³

Trauma centers work within a larger trauma system to provide specialized regional care to injured patients. In most states, trauma centers meeting stated criteria become “verified” to deliver a specified level of care based on available resources. Level 1 trauma centers are considered the highest verification level and provide comprehensive, multidisciplinary care to injured patients. Verified trauma centers also participate in regional, state, and national quality improvement initiatives by reporting their data. Trauma centers also frequently participate in research to advance the care of injured patients.

It is well recognized that trauma systems and dedicated trauma centers improve outcomes and reduce mortality secondary to injury. Trauma centers with specialized expertise in pediatric trauma continue to show advantages for injured children when compared to other centers without such expertise.⁴ For example, there is strong evidence that children with identified traumatic brain injury (TBI) should be transported directly to an available pediatric trauma center. Pediatric injury requires dedicated expertise, and children have improved outcomes with reduced mortality when admitted directly from the injury scene compared to those admitted by hospital-to-hospital transfer.⁵

The trauma team is a fundamental component to a trauma center’s mission of caring for injured patients. The trauma team refers to all who care for the trauma patient, from the initial resuscitation to hospital discharge. Members of the trauma team include trauma surgeons, ED physicians and nurses, critical care physicians and nurses, subspecialty surgeons, radiologists, social workers, and occupational, physical, and respiratory therapists. Other healthcare personnel may also be included in the trauma team, such as clergy, mental health specialists, and rehabilitation physicians. For optimal function, trauma teams

require strong hospital commitment and support. Additionally, policies and protocols that are understood and adhered to by all team members should be in place. The initial resuscitation team is usually led by a surgeon and performs best when led by an attending trauma surgeon. The prepared trauma team improves performance in resuscitation as well as outcome of the patient.⁶ The pediatric critical care physician also plays an important role in the pediatric trauma team. The pediatric critical care physician has expertise in life-support therapies including mechanical ventilation, renal replacement therapies, and treatments to prevent secondary brain injury. Together, the trauma surgeon and critical care physician should lead a multidisciplinary team with daily rounds in the pediatric intensive care unit (ICU). Such teams should include all necessary trauma team members and work to develop treatment algorithms and protocols. There is mounting evidence that this approach leads to improved outcomes in pediatric trauma and is soon becoming the standard of care.

INITIAL TRAUMA ASSESSMENT AND RESUSCITATION

Initial resuscitation begins in the field with emergency medical service personnel and continues at the trauma center with the designated trauma team. Resuscitation follows the priorities outlined in the ACS Advanced Trauma Life Support (ATLS®) protocol. While special consideration is given to anatomic and physiologic differences of children, the priorities of resuscitation remain the same as those in adults. It is recommended that all trauma team members participating in the initial assessment and resuscitation have ATLS certification. The basic principles of the initial assessment will be briefly reviewed below.

A primary survey is conducted to rapidly assess the patient and identify all potential life-threatening injuries. The primary survey is usually referred to as the ABCDEs (airway, breathing, circulation, disability, and exposure) of trauma. The first priority remains assessment of the airway for patency and maintainability and cervical spine stabilization. Patients with obvious head trauma or who have an altered level of consciousness (Glasgow Coma Scale [GCS] score ≤ 8) require airway protection. Adequate airway control must be obtained while maintaining cervical spine immobilization. When intubation is required, most trauma patients should be orally intubated with direct cricoid pressure, and the most experienced clinician should perform intubation. Many pharmacologic agents are available for rapid-sequence intubation (RSI), similar to adult resuscitation. Doses are adjusted for patient weight, and guidelines are available on the Broselow® tape. The reason for intubation as well as the types of injuries present dictate the medications used. Tracheal tube placement should be confirmed by end-tidal carbon dioxide monitoring, by auscultation of the abdomen and both sides of the chest, and by a chest radiograph. The patient’s heart rate, blood pressure, oxygen saturation, color, and perfusion should be continuously monitored. Once the airway is secure, ventilation should be evaluated. Evaluation of unequal breath sounds with a correctly positioned endotracheal tube should raise concern for a hemothorax or pneumothorax. Tracheal deviation, though rare, may help with the diagnosis of tension pneumo- or hemothorax. Breath sounds are transmitted easily in children, and a simple pneumothorax is often not apparent until a chest radiograph is obtained. Tube thoracostomies are placed as needed. Flail chest is rare

in children owing to the flexibility of the rib cage. Ventilation should be maintained with 100% oxygen during resuscitation.

After successful airway establishment and ventilation, the circulation must be assessed. Direct pressure should be applied to any site of the active hemorrhage. Pulses, perfusion, capillary refill, heart rate and rhythm, and blood pressure should be evaluated. Intravenous (IV) access, preferably two large-bore catheters, must be obtained rapidly for volume resuscitation. Intraosseous access or venous cut-down should be considered if peripheral access is difficult to obtain. Young children have vigorous compensatory mechanisms and will preserve blood pressure despite losing more than 25% of their circulating blood volume.^{7,8} For this reason, significant injury-related hemorrhage (e.g., intraabdominal) may be a life-threatening condition. The heart rate is the most sensitive indicator of hypovolemia in pediatric trauma patients. Thready pulses and altered mental status are evident with a loss of 30% to 45% of blood volume and represent a dangerous scenario as cardiovascular collapse will be imminent. Volume resuscitation begins with crystalloid at 20 mL/kg, with further volume boluses based on the patient's response. Blood products may be necessary to stabilize patients with hemorrhagic shock. Resuscitation with red blood cells, plasma, and platelets in a ratio of 1:1:1 along with appropriate use of coagulation factors such as cryoprecipitate, as well as rapid surgical control, may be necessary for ongoing hemorrhage. The attending pediatric surgeon should direct the resuscitation of a pediatric patient with active hemorrhage. All infused fluids and blood products should be warmed as pediatric patients are at high risk of hypothermia.

Hypotension contributes to secondary injury to the brain and other vital organs and must be treated aggressively. In rare cases, vasoactive agents may be necessary in the resuscitation room. Trauma victims who are pulseless at the scene have an almost uniformly fatal outcome.^{7,9} Prolonged, heroic resuscitative efforts should be avoided in these patients. Patients who have a pulse at the scene but suffer a cardiac arrest en route or in the ED have a slightly better prognosis, and resuscitation should be attempted. Most cardiac arrests associated with blunt trauma are a result of multisystem injuries, including severe brain injury.¹⁰ Open chest resuscitation should be considered only in the rare case of penetrating chest trauma as it has been shown to be of no benefit in blunt trauma.

Disability should include a brief neurologic examination focusing on the level of alertness, GCS score, pupillary response, focal signs of spinal cord injury, and signs of increased intracranial pressure (ICP). Subjects with a GCS score of 8 or less or with a waning mental status should be intubated using RSI. Patients with a suspected head injury need rapid assessment, and noncontrast head computed tomography (CT) should be performed promptly. All trauma patients are undressed and exposed for a full examination. The patient should be log rolled to inspect the spine and back and complete the assessment of obvious injuries. A rectal examination should only be performed one time when clinically appropriate as determined by the attending pediatric surgeon. Children lose heat due to their increased body surface area to volume ratio and should be warmed with lights and blankets. The resuscitation room temperature must be increased to prevent hypothermia.

Following the primary survey and stabilization, necessary laboratory studies are performed, and radiology studies including a chest x-ray and pelvic x-ray should be obtained. The secondary survey then commences with a full head-to-toe physical examination. Injuries are documented, necessary consultations are placed, and the team decides on the disposition of the patient.

Specific Injuries and Critical Care Management

Closed Head Injuries

Closed head injury or TBI is the leading cause of death in pediatric trauma, with nearly 3000 deaths annually. Childhood TBI survivors often have life-long morbidities and impairment.¹¹ Linear and inertial forces resulting in an impact injury cause the primary injury in TBI.¹² These injuries include hematomas, lacerations, and axonal shearing,

and are often described as irreparable. Secondary injury refers to the injury that occurs after impact and is considered both preventable and potentially reversible. Pathologic alterations in respiratory, hemodynamic, and cellular function occur, which may lead to secondary injury and cell death. The pathways to neuron death include inadequate oxygen and nutrient supply secondary to hypoxia and decreased cerebral blood flow. Decreased cerebral blood flow can occur secondary to hypotension, decreased cardiac output, raised ICP, cerebrovascular dysregulation including vasospasm, and microthrombus formation. Elevated ICP occurs secondary to mass lesions, cerebral edema, and increases in cerebrospinal fluid and blood volumes. Other neuronal injuries occur secondary to inflammation, oxidative stress, and apoptosis. Present TBI therapies are directed primarily at supporting oxygenation, blood pressure, and cardiac output and at controlling ICP to prevent secondary injury.¹²

Despite insufficient evidence for definitive treatment standards in TBI, a number of guidelines have been recommended.¹³ These include early admission with severe TBI to a pediatric trauma center, avoidance of hypoxia, correction of hypotension, and maintenance of cerebral perfusion pressure greater than 40 mm Hg in children. There is little evidence to support the routine use of corticosteroids or the prophylactic use of antiseizure medication. Currently, a number of National Health Institute multicenter trials are under way to better elicit treatment recommendations in pediatric TBI.

Initial stabilization and resuscitation follow the ATLS protocol. The underlying goal is airway protection and respiratory support to prevent hypoxemia and hypercarbia. Hyperoxia and brief, aggressive hyperventilation is indicated only if the clinical examination reveals signs of acute cerebral herniation. These maneuvers should be directed by neurosurgery and are usually initiated immediately before operative intervention. Normotension or mild hypertension and mild hypervolemia are indicated to support cardiac output and cerebral blood flow. Fluids, sedation, and vasoactive agents must be judiciously administered. Hypertonic saline may be advantageous in children with elevated ICP. All children with a suspected TBI, history of loss of consciousness, altered level of consciousness, focal neurologic signs, evidence of a depressed or basilar skull fracture, a bulging fontanelle, or persistent headache and vomiting should have a noncontrast head CT.¹³ Early consultation with neurosurgery is indicated in all children with significant TBI. ICP monitoring should be considered in patients with a GCS score less than 8. Even with a normal CT scan, 10% to 15% of patients with a GCS ≤ 8 have elevated ICP. ICP monitoring with a ventricular catheter, an external strain gauge transducer, or a catheter tip pressure transducer is considered accurate and reliable. Ventriculostomy allows cerebrospinal fluid drainage in addition to ICP monitoring.

ICP in children and adolescents should be kept at less than 20 mm Hg. In young infants with open fontanelles and sutures, and in older children with large diastatic skull fractures, controlling the ICP at less than 10 to 15 mm Hg may be prudent. The guidelines recommend a cerebral perfusion pressure greater than 40 mm Hg in children with TBI, although it may be better to maintain cerebral perfusion pressure according to an age-related continuum between 45 and 70 mm Hg.

Initial treatment for elevated ICP includes sedation and analgesia, ventriculostomy drainage, and muscle relaxants. Sedation can be accomplished with low-dose fentanyl, dexmedetomidine, and intermittent doses of benzodiazepines or barbiturates. If ICP is not controlled, a repeat CT should be obtained and hyperosmolar therapy begun. Osmolar agents include mannitol and hypertonic saline. Hypertonic saline appears to have several advantages over mannitol, allowing for a consistent control of osmolality and minimizing ICP spikes.^{13,14} Additionally, hypertonic saline supports mean arterial pressure and cardiac output, has beneficial vasoregulatory properties, and may have beneficial effects on inflammatory responses. Hypertonic saline (3%) is administered as a continuous infusion, and the appropriate dose is the minimum dose required to keep ICP less than 15 to 20 mm Hg. The dose may be increased provided that serum osmolality is less than 360 mOsm/L.¹⁵

Neck Injuries

Injuries to the airway in children can be rapidly life threatening. Small airway diameter combined with penetrating or blunt injury to the neck can produce rapid airway obstruction. Children are at greater risk than adults for spinal and major vascular injury from neck trauma.

Clinically, the neck is divided into three anatomic zones. Zone 1 extends from the level of the clavicles up to the cricoid cartilage. Injuries to this area may involve the apex of the lung; trachea; subclavian, carotid, and jugular vessels; thoracic duct; esophagus; vagus nerve; and thyroid gland. Patients suffering zone 1 injuries typically exhibit hypotension because the great vessels are often injured. Zone 2 encompasses the area from the cricoid cartilage to the mandible, and injuries to this area are the easiest to detect. Active bleeding can be reduced by direct pressure. Zone 2 penetrating injuries can be managed with selective surgical exploration of the wound after clinical, endoscopic, and radiographic evaluation. Zone 3 extends from the angle of the mandible to the base of the skull. The oropharynx, jaw, and teeth are located within this area. Mandibular fractures in children manifest as malocclusion of the biting surfaces of the teeth and are usually associated with dental injuries. Injury to the chin associated with tympanic membrane perforation or hemotympanum is associated with an occult fracture of the mandible. Orotracheal intubation is not usually problematic in children with mandibular fractures unless there is copious oral hemorrhage.

Penetrating neck and airway injuries occur less frequently in children than in adults, with the majority of these injuries occurring in adolescent males. Penetrating injuries can be lethal owing to the important anatomic structures injured, such as a bullet injury to the major vascular structures. As a result, penetrating wounds to the face and neck are more likely to require surgical intervention than blunt injuries. The extent of damage to deep tissues may not be apparent on examination of the wound site. Stab wounds typically produce linear tissue injury that follows a predictable path from the entrance wound into the deeper tissue, whereas ballistic injuries often produce unpredictable tissue damage as they progress through the neck. Penetrating injury to any of the major systems usually results in rapid airway compromise and shock.

Penetrating injury to the esophagus may not be immediately apparent but can produce delayed morbidity due to mediastinitis. Investigation of neck injuries that involve the trachea should always include evaluation of the esophagus for perforation. Esophageal perforation should be suspected if fever, elevated white blood cell count, and subcutaneous air in the neck occur in the days following a traumatic neck injury. Management of the perforation requires prompt surgical repair of the esophagus, drainage of the surrounding soft tissue infection, and IV antibiotics.

Blunt neck injuries are less common than penetrating injuries and can be associated with life-threatening airway disruption.^{16,17} Blunt neck trauma is also associated with injuries to the cervical spine, esophagus, lungs, and great vessels. Mortality rates of up to 30% are reported for children with these injuries, and half of these children die of tracheobronchial rupture within 1 hour of the injury.¹⁸

Blunt laryngeal trauma in children is uncommon and frequently unrecognized. The clinical presentation of laryngeal injury in children includes frank respiratory distress with hoarseness, stridor, and palpable subcutaneous emphysema.¹⁶ Radiographs of the chest and neck may show subcutaneous emphysema. The diagnosis of blunt laryngeal trauma in children is based on history, physical examination, and radiographic studies, followed by flexible or rigid bronchoscopy. CT of the neck adds little to the diagnosis of laryngeal injury. Once a laryngeal injury is suspected, rigid endoscopy in the operating suite should be used to secure the airway as well as delineate and repair the injury.

Thoracic Injuries

Thoracic trauma accounts for 5% to 10% of admissions to trauma centers and carries a 5% mortality rate. However, the mortality rate increases fivefold when there is concomitant head or abdominal injury

and can exceed 40% when a combination of head, chest, and abdominal injuries are present.¹⁹ Potentially life-threatening injuries including airway obstruction, tension pneumothorax, massive hemothorax, open pneumothorax, flail chest, and cardiac tamponade must be corrected immediately. Young children (<8 years of age) have a significantly more flexible thoracic cage compared to adults. As a result, compression of intrathoracic organs by blunt trauma may lead to significant parenchymal injuries in the absence of rib fractures. Thus, pulmonary contusions, rather than broken ribs, are far more common in children. An isolated first rib fracture, however, is a potential sign of child abuse or may be associated with significant thoracic injury.¹⁹ Multiple rib fractures should alert the clinician to look for underlying injuries in the thoracic cavity. Further radiographic evaluation directed by the attending pediatric surgeon, such as CT angiography, may be warranted to complete the diagnostic evaluation. Supportive care is the mainstay of rib fracture management. Appropriate analgesia is necessary to promote deep inspiratory effort and prevent atelectasis.

Failure of tube thoracostomy to reexpand the lung and the continued presence of a large air leak denote a tracheal or bronchial disruption. If the site of tracheal or bronchial disruption is within the chest cavity, the endotracheal tube tip should be placed distal to the disruption. This may require bronchoscopy. Selective intubation of the undisrupted main stem bronchus, followed by one-lung ventilation, is a temporizing measure until the operative repair can be performed. An experienced physician should rapidly and cautiously attempt main stem intubation to avoid extending the tracheal injury.

Pulmonary contusion may occur with or without the presence of overlying rib fractures or chest wall injury. Symptoms include tachypnea, dyspnea, cyanosis, hemoptysis, and respiratory failure. The initial chest radiograph may not demonstrate this injury, and repeat x-rays may be necessary to reveal the infiltrates. Judicious IV fluids should be administered. Acute respiratory distress syndrome (ARDS), while uncommonly associated with pulmonary contusion, may develop and require mechanical ventilation.

In children, the mediastinum is less fixed than in adults, and the physiologic consequences of tension pneumothoraces, hemothoraces, or hemopneumothoraces will be rapidly evident. In children, each hemithorax can hold 40% of a child's blood volume and may be a source of hemorrhagic shock. A chest tube large enough to drain the entire hemithorax without clotting or occluding is necessary. Surgical exploration for hemostasis may be required if the initial chest tube output is 20 mL/kg or greater than 3 to 4 mL/kg/h.²⁰ Inadequate evacuation may lead to lung entrapment and predisposes the patient to chronic atelectasis. Anterior penetrating injuries below the nipple line and posterior penetrating injuries below the tip of the scapula warrant exclusion of intraabdominal injuries. Penetrating injuries often require thoracotomy in the operating room.

Other rare thoracic injuries include traumatic asphyxia and esophageal tears. Traumatic asphyxia is caused by sudden, severe compression of the chest and upper abdomen and is characterized by craniofacial and cervical cyanosis, edema, and petechiae. Additionally, subconjunctival and thoracic wall petechiae occur, and there may be associated respiratory distress, cardiac arrest, and cerebral edema with raised ICP.²¹ Esophageal lacerations occur in less than 1% of children with blunt thoracic injuries and can be diagnosed with flexible esophagoscopy. Esophageal lacerations almost always require operative repair.²²

Cardiac and Aortic Injuries

Traumatic injury to the heart and great vessels is uncommon in pediatric patients, and most of the injuries are the result of blunt trauma. Myocardial contusion results from blunt force injury to the chest. The vast majority of pediatric patients with myocardial contusions have multisystem trauma; pulmonary contusion is the most common coexisting injury, found in 50% of patients.²³ Hemodynamically significant myocardial contusions are rare in pediatric patients and present with arrhythmia or ventricular dysfunction. Patients presenting with a normal sinus rhythm have not been shown to develop arrhythmias or cardiac failure. Diagnostic evaluation of myocardial

contusion is controversial in pediatrics, and testing may include a combination of cardiac enzyme determinations, electrocardiography, and echocardiography. Creatine kinase-MB and cardiac troponin-I elevation following blunt trauma has been used to diagnose contusion. Cardiac troponin-I is highly specific for the myocardium, and elevation of troponin-I occurs within 4 hours of injury and peaks within 24 hours. The significance of cardiac enzyme elevation in a hemodynamically stable patient is unclear, and determination may not be necessary in these patients.²⁴ An admission 12-lead electrocardiogram (ECG) is recommended in all patients. Echocardiography is useful for the diagnosis of cardiac injury in patients with hemodynamic instability who had nondiagnostic ECG.

In addition to myocardial contusion, structural damage such as traumatic ventriculoseptal defect, valve injury, ventricular rupture, or aneurysm may occur with blunt chest trauma. The management of all blunt cardiac injury is largely supportive, with operative intervention as needed for significant structural damage. Continuous ECG monitoring is recommended.

Comotio cordis is an unusual event but is much more common in pediatric patients, with 50% of victims younger than 14 years. Blunt trauma to the chest with the impact centered over the heart results in immediate cardiac arrest. It is thought that the narrow anteroposterior diameter of the chest, in conjunction with the increased compliance of the chest wall in pediatric patients, allows a chest-wall blow to be transmitted to the underlying heart. Many, but not all, cases occur during sports-related activity.²⁵ Blunt chest trauma leads to cardiovascular collapse, with ventricular tachyarrhythmia being the most common arrhythmia. Unlike myocardial contusion, there is no evidence of myocardial injury on autopsy. The survival rate is low, even with prompt resuscitation.²⁶

Blunt aortic injury is an extremely uncommon pediatric injury; however, as in adults, it is potentially lethal. The aortic arch is relatively fixed, and the descending aorta is more mobile, making it susceptible to shearing forces during horizontal and vertical deceleration. Diagnosis of thoracic aortic injury is similar in children and adults. The pattern of chest x-ray findings is similar. CT angiography is an important diagnostic tool and has sensitivity and specificity approaching that of angiography for the diagnosis of thoracic aortic injury.²⁷ Transesophageal echocardiography may also have a role in diagnosis, although it is an invasive procedure and requires additional expertise in interpretation. As in adults, successful management of potentially lethal aortic injuries depends on prompt recognition and surgical treatment.

Abdominal Injuries

More than 90% of abdominal trauma in children is the result of blunt trauma. Following initial evaluation and resuscitation as outlined by the ACS ATLS protocol (described above) the process of identifying specific injuries commences. It is critical to know the mechanism of trauma in order to appreciate patterns of potential abdominal injuries. In children with a suspected intraabdominal injury, a nasogastric or orogastric tube should be placed following the primary survey because dilatation of the stomach may lead to vomiting and potential aspiration injury. Similarly, a urinary catheter should be placed after inspection of the pelvis and perineum to monitor urine output and evaluate fluid resuscitation. Inspection of the abdomen may reveal external evidence of trauma suggestive of an underlying injury.

Evaluation of abdominal tenderness is important and, when present, is a significant finding. While a number of injuries may cause abdominal pain, including lower rib fractures, contusion or soft tissue injury to the abdominal wall, or pelvic fracture, it is imperative that intraabdominal injury be thoroughly investigated. The pelvis should be examined by compression. Rectal examination should be selectively performed in children. Rectal examination is rarely indicated in smaller children unless there is a specific concern (e.g., spinal cord injury or rectal injury). Children with pelvic fractures, bruising to the perineum, blood at the penile meatus or blood in the diaper/underwear should have a documented rectal examination performed by an

experienced pediatric specialist. Hematuria is indicative of genitourinary injury.

The gold standard for evaluation of children with blunt abdominal trauma is CT with IV contrast. It gives reliable information about solid-organ injuries, the presence of abnormal fluid, the presence of pneumoperitoneum indicating hollow viscus injury, and the retroperitoneal space. The high sensitivity and specificity of CT scanning and the successful use of nonoperative solid-organ injury have essentially replaced diagnostic peritoneal lavage (DPL) in blunt abdominal trauma. The use of DPL is rarely indicated and should only be considered in consultation with a pediatric surgeon. Penetrating injury is generally rare in pediatrics. Virtually all gunshot wounds to the abdomen and lower chest should be treated by mandatory laparotomy or thoracotomy. Stab wounds below the nipple line and above the inguinal ligament require surgical evaluation. Unlike in adults, stab wounds in pediatric patients may be amenable to nonoperative management. In general, these wounds require careful examination and local wound exploration performed by an experienced surgeon. If there are concerns for intraabdominal injury, CT scanning may be beneficial. Alternatively, diagnostic laparoscopy can be considered to evaluate for intraabdominal injury. The advantage of diagnostic laparoscopy is that many injuries are amenable to laparoscopic treatment in experienced hands.²⁸

Liver. Signs and symptoms of hepatic injury include pain and tenderness, abrasions, and contusion of the abdominal wall. Signs of peritonitis due to hemoperitoneum are frequently present. Most isolated liver injuries can be managed nonoperatively. Selective angiography and embolization may be considered to attempt control of bleeding. While angiography may be useful in older children and adolescents, it should be used with caution in younger children (less than 5 years of age). The small vessel size of smaller children may lead to unintended injury or complications. Consultation with the attending pediatric surgeon is mandatory in this decision-making process. Operation may be required for hemodynamic instability, continued transfusion requirements, or other associated injuries. The decision to operate is based on the child's physiologic status and not the graded classification of injury.²⁹ Complications of hepatic injury include hemobilia, abscess, biliary fistula, and bile peritonitis.

Spleen. The spleen is the organ most frequently injured in blunt abdominal trauma. Ecchymosis, pain, and tenderness over the left upper quadrant are suggestive of splenic injury. Left shoulder pain may be present as a result of diaphragmatic irritation. Abdominal CT is recommended to determine the extent of injury as well as the presence of hemoperitoneum and other associated injuries. Nonoperative management is preferable and is similar to the nonoperative management of liver injuries. Surgical management may be necessary in patients who are hemodynamically unstable, require continued transfusions, or have other associated abdominal injuries. A variety of surgical techniques are available to control bleeding, often without a total splenectomy.³⁰ In patients requiring total splenectomy, there is a risk of overwhelming postsplenectomy infection (OPSI). OPSI may occur at any time following splenectomy, but the risk is greatest in the first 5 years of life and carries a high mortality. All postsplenectomy patients must be immunized, and the use of prophylactic antibiotics is recommended.

Duodenum and Pancreas. The duodenum and pancreas are fixed retroperitoneal structures that are frequently injured by a blunt force trauma (e.g., handlebar injury) to the mid-epigastrium. The diagnosis of pancreaticoduodenal injuries is challenging and begins with evaluation of chemical markers and imaging studies. Serum amylase and lipase are indicators of pancreatic injury, but amylase levels may be elevated due to injuries to other organs (e.g., salivary glands). Ultrasonography and CT are the preferred imaging studies to delineate the pancreas. Recently, magnetic resonance cholangiopancreatography (MRCP) has been used to delineate pancreatic body and ductal injuries. Duodenal perforations can be diagnosed using upper GI studies with water-soluble contrast or CT scan with oral contrast. Most pancreatic injuries are mild and can be managed nonoperatively with

nasogastric decompression and parenteral nutrition.³¹ Management of patients with severe pancreatic injuries is controversial. Patients with severe pancreatic injury may require surgical repair or endoscopic placement of pancreatic duct stents. Several complications may occur after pancreatic injury, including pleural effusion, bile duct obstruction, and pancreatic pseudocyst formation. Most duodenal injuries are lacerations that can be treated by simple débridement and primary repair. Duodenal hematoma results from blunt abdominal trauma associated with rapid deceleration or from a direct blow to the upper abdomen. It may present a day or more after injury as vomiting or as a large amount of nasogastric drainage. The resultant intestinal occlusion should be treated by nasogastric decompression and parenteral nutrition until the obstruction resolves.

Small Intestine. Hollow viscus injuries are far less common than solid-organ injuries in pediatric abdominal trauma patients. The mechanism of injury is either compression or shear forces resulting from rapid deceleration. There are two points of fixation to the retroperitoneum that frequently lead to transections: the ligament of Treitz and the cecum. Handlebar blows or direct blows to the abdomen compress the bowel against the vertebral column, resulting in intestinal perforation. In the seat-belt complex, contusions or abrasions of the abdominal wall and lumbar spine injury are associated with bowel perforation. Upper lap belt loading is associated with liver, spleen, rib, stomach, small bowel, and large bowel injuries. Lower lap belt loading is associated with ribs, small bowel, large bowel, bladder, kidney, and stomach injury.³²

Identification of patients with a bowel injury is often challenging. Obtaining a detailed history of the mechanism of injury, careful physical examination, and a high degree of suspicion will often identify injuries. Detection of peritoneal signs may be difficult owing to distracting pain from the abdominal wall and back injury. There is no completely reliable imaging study available to detect intestinal injury. CT may show nonspecific findings suggestive of bowel injury. Serial clinical examinations, monitoring vital signs and fever curves, and repeat laboratory studies are often adequate for experienced clinicians to diagnose intraabdominal injury. Patients should remain NPO until a bowel injury is no longer suspected.

Diaphragm. Diaphragmatic rupture is the consequence of direct blunt trauma over the lower thorax and abdomen and is most frequent on the left side. Contusions or abrasions of the upper abdomen, bowel sounds in the chest, and respiratory distress are the classic findings of a traumatic diaphragmatic rupture. A chest radiograph is the initial study and may show bowel and/or the nasogastric tube in the thorax. The diagnosis of diaphragmatic rupture may be confirmed by ultrasonography, CT, and/or intraoperatively with thoracoscopy/laparoscopy. Laparotomy allows proper repair of the diaphragmatic defect and assessment of other organs.

Abdominal Damage Control Surgery. If the injured child remains hemodynamically unstable despite aggressive resuscitation, a laparotomy for damage control may be required.³³ Hypothermia, acidosis, and coagulopathy are considered a lethal triad, and surgical intervention may be unwarranted.³⁴ Abdominal damage control surgery has three stages. The first stage is the initial laparotomy with the goal to control hemorrhage and prevent ongoing damage. Abdominal packing and temporary closure of the wounds with loose retention sutures or an abdominal wound vacuum device can be utilized. The second stage is continued in the ICU, with the goals of continued resuscitation, active warming of the patient, correcting any coagulopathy present, and restoring acid-base balance. Intraabdominal pressure may become elevated secondary to edema, tissue swelling, ascites, and ongoing bleeding. These increased pressures are often referred to as abdominal compartment syndrome and may cause cardiorespiratory and renal deterioration. Increased abdominal pressure may also cause hypoperfusion of the abdominal contents, leading to renal failure and ischemic bowel injury. Additionally, as abdominal pressure rises, venous return may be impaired, thus impacting and reducing cardiac output. Treatment of abdominal compartment syndrome is urgent and may require a peritoneal drain or opening of the abdominal wound

and placement of a silo or suction device.³⁵ The third stage involves definitive operative repair of all injuries once the patient is stabilized.

Genitourinary Injuries

Genitourinary trauma is common and occurs in 12% of injuries in children. The unique characteristics of a child's anatomy predispose to genitourinary trauma. The kidneys are proportionally larger, the abdominal musculature underdeveloped, and the ribs less ossified compared to adults. In addition, the underdeveloped renal capsule and Gerota's fascia increase the likelihood of laceration, hemorrhage, and urine extravasation.

The majority of injuries are due to blunt force trauma and have a high association with pelvic trauma. Preexisting renal disease predisposes to renal injury and is found in 20% of cases of documented renal trauma. Findings suggestive of genitourinary trauma include flank or abdominal tenderness, perineal injury, blood at the urinary meatus, mobile or displaced prostate, and gross hematuria.

Similar to splenic and liver injuries, renal injuries are graded based on severity determined by imaging studies. Parenchymal injuries not involving the collecting system or renal vessels constitute 85% of renal injuries, whereas injuries to the collecting system or renal vessels account for 10% of renal injuries. The most severe injuries account for the remaining 5% of renal injuries and include a shattered or devascularized kidney.

Minor injuries rarely require surgery and are treated expectantly. Limited hospitalization with decreased activity until hematuria has resolved is typically all that is required, and imaging at 6 to 8 weeks following discharge is recommended.³⁶ Surgical intervention should be reserved for patients with major injuries and hemodynamic instability from persistent bleeding. The management of major injuries in patients who have normal vital signs is controversial. Even in the case of urine extravasation without urethral injury, expectant treatment with repeat imaging studies at 5 to 7 days is acceptable, and nonoperative management of pediatric renal trauma has become the preferred approach in managing blunt renal injuries.³⁷

Penetrating renal injuries secondary to gunshot wounds should be explored because of the high incidence of associated injuries. Surgical treatment for stab wounds with suspected renal involvement should be based on the severity of hemorrhage as well as clinical and imaging evidence suggesting intraabdominal injury.

Renovascular injuries generally occur in patients who have sustained life-threatening multisystem injuries. The mechanism of renovascular injury is thought to be deceleration and occurs more frequently on the left side. The diagnosis is established with contrast-enhanced CT. Successful revascularization depends on the length of renal ischemia, extent of vascular injuries, and extent of associated injuries. Repair of penetrating renal artery injuries is most successful if the ischemic time is less than 8 hours. Blunt arterial injuries are associated with the lowest rate of renal preservation and may be treated by nephrectomy when they are unilateral in a symptomatic patient.

Pelvic Fractures

Pelvic fractures are a marker of significant trauma and are often associated with other injuries. Pelvic fractures occur in approximately 2% of all blunt abdominal injuries, and 20% of those with pelvic fractures have intraabdominal injuries. Mortality varies from 10% to 50% and is often due to associated injuries. The most common mechanisms are falls, crush injuries, and motor vehicle accidents. Clinically, the diagnosis is suggested by pain with anterior or lateral compression of the pelvis, although other findings may include perineal ecchymosis, blood at the urinary meatus or on the rectal examination, disruption of the rectal wall with mass effect due to bony fragments, or displacement of the prostate.

Evaluation of pelvic trauma begins with a pelvic radiograph and should include CT. Treatment usually consists of bed rest, immobilization, and blood loss replacement. Severe injuries with significant blood loss may require prompt intervention and immobilization such as wrapping the pelvis with a bed sheet or application of an external

fixation device. Treatment is dependent on the type and severity of the injury. Orthopedic surgery should be consulted early to help define the best treatment.

Spinal Injuries

Approximately 5% of all spinal cord injuries occur in the pediatric age group. Common causes in young children include falls and motor vehicle accidents.³⁸ For older children, sports, other recreational activities (e.g., diving, horseback riding), and gunshot wounds have greater etiologic importance.

Maintaining neutral cervical alignment during transport and initial resuscitation of a child at risk of a spinal injury is critical. An appropriately sized cervical collar should be used, and often a support can be placed under the thorax to achieve elevation of the torso to maintain spinal immobilization.

Initial assessment dictates the need for imaging studies. An awake, communicative child without midline cervical tenderness, intoxication, decreased level of consciousness, focal neurologic deficit, or a painful, distracting injury does not require spinal imaging studies. Cervical spine imaging studies include lateral C-spine, anteroposterior (A-P) C-spine, open-mouth views, flexion/extension lateral C-spine radiographs, CT, and magnetic resonance imaging (MRI). For the child with symptoms of cervical spine and/or cervical cord injury, as well as for the comatose child, CT imaging and/or MRI are now recommended.³⁹

Recent studies show no benefit of high-dose methylprednisolone for complete and incomplete spinal cord injury.⁴⁰ In a child with a spinal cord injury, emphasis is placed on maintenance of optimal physiologic homeostasis. Because of loss of sympathetic tone, IV pressor agents are frequently required in addition to crystalloid and colloid solutions to maintain age-appropriate blood pressure and cardiac output. Intubation may be necessary with high cervical spine injuries because of respiratory compromise. Avoidance of unnecessary neck manipulation is mandatory.

After initial resuscitation and the identification of spinal injuries, urgent neurosurgical consultation is indicated. Closed reduction and initial stabilization of these injuries are frequently performed in the ICU. Halo rings can be placed with acceptably low morbidity in the ICU setting, even in infants; they can be attached to weighted traction mechanisms for closed reduction if necessary and converted to halo jackets to maintain alignment. The need for and timing of internal surgical stabilization should be discussed in the context of the child's concomitant multisystem issues.

Organ Failure

Respiratory Failure

Trauma can result in lung injury and respiratory failure, the most severe of which is acute respiratory distress syndrome (ARDS). Post-traumatic respiratory failure results from both direct and indirect injury to the respiratory system. Direct injuries include aspiration of gastric contents, near-drowning, smoke inhalation, and pulmonary contusion. Lung injury also occurs indirectly as a consequence of systemic insults such as hemorrhagic shock, sepsis, massive transfusion, fat embolism syndrome, or the systemic inflammatory response syndrome (SIRS). ARDS is an acute and progressive respiratory disease of a noncardiac nature associated with diffuse bilateral pulmonary infiltrates and hypoxemia. The definition includes a ratio of arterial oxygen tension (P_{aO_2}) to inspired oxygen fraction (F_{iO_2}) less than 200.

The pathologic findings in ARDS are the result of a complex sequence of cellular and biochemical changes that lead to damage of the endothelial membranes. The complex roles of leukocytes, complement activation, prostaglandin release, oxygen radicals, and other mediators of vascular damage are currently under investigation. However, neutrophils are an important mediator of lung tissue damage. Blunt trauma enhances the migratory capacity of neutrophils in response to interleukin-8, potentially increasing the risk of ARDS.⁴¹

ARDS management in the field of pediatrics has focused on minimizing iatrogenic lung injury and on adjuncts to mechanical ventilation. Both oxygen and mechanical ventilation can be injurious to the lung. Oxygen causes oxidative damage and absorptive atelectasis, with chronic exposure to high inspired concentrations of oxygen creating pathology indistinguishable from ARDS. Toxic reactions to oxygen occur commonly with the use of F_{iO_2} greater than 50%, and these effects worsen when excessive oxygen is used for longer than 24 hours. Mechanical ventilation also causes lung injury due to barotrauma as a result of shearing forces applied in the terminal airways. The higher the tidal volumes used to ventilate patients, the greater the stresses and the larger the risk of secondary lung injury. These stresses on the terminal airways and pulmonary endothelium further incite pulmonary edema, surfactant dysfunction, decreased compliance, hyaline membrane formation, and impairment of gas exchange.

Ventilation strategies focus on decreasing iatrogenic lung injury by limiting oxygen concentration and decreasing barotrauma. Permissive hypercapnia (allowing P_{CO_2} 45 to 60 mmHg or higher) is also practiced when the patient's condition allows. The strategy of "gentle" ventilation has been shown to decrease morbidity and mortality in pediatric ARDS.^{42,43} The strategy for low-volume, low-pressure ventilation comes from the National Institutes of Health ARDS Network trial comparing 6-mL/kg versus 12-mL/kg tidal volumes in patients with ARDS. Mortality in the low-tidal volume group was 31.3%, versus 39.8% in the higher tidal volume group.⁴⁴ Similar pediatric research using a high-rate, low-tidal volume (3 to 5 mL/kg) strategy in children with severe ARDS demonstrated a survival rate approaching 90%.⁴⁵ Hypercapnia is typically well tolerated, except in patients with TBI with intracranial hypertension or those with severe pulmonary hypertension. For patients who fail support with mechanical ventilation, extracorporeal membrane oxygenation (ECMO) support may be utilized if there are no contraindications (e.g., ongoing bleeding). Consultation with the pediatric ECMO team is warranted early in the course of respiratory failure. Early consultation in conjunction with the pediatric surgery and pediatric ICU teams will allow for determination of eligibility for ECMO, prepare for possible cannulation and to discuss expectations with the family. While there have been a number of adjuncts to ventilation proposed, including the use of prone positioning, inhaled nitric oxide (iNO), surfactant, steroids, immunomodulation, or antiinflammatory agents, the evidence for the use of these adjuncts is lacking and remains under investigation. For example, iNO is known to be a potent pulmonary vasodilator, and its use has been proposed for pediatric ARDS. In patients with documented pulmonary hypertension and/or right ventricular failure, the use of iNO may be attempted. Current evidence suggests that iNO increases P_{aO_2} levels, but has not been shown to confer a survival advantage. The use of inhaled NO delivered during high-frequency oscillatory ventilation (HFOV) in patients with ARDS resulted in a significant increase in arterial oxygenation.⁴⁵

Shock

Children sustaining trauma develop shock most commonly as a direct result of hemorrhage, but shock can also be the result of tension pneumothorax, spinal cord injury, cardiac tamponade, myocardial contusion, or sepsis. Direct tissue injury and hemorrhage play roles in early shock, while inflammation and altered immune function can result in SIRS, multiple organ failure, and septic shock later in the disease course.

Children have remarkable compensatory mechanisms in response to hypovolemia. Children maintain cardiac output by increasing heart rate more than the stroke volume. Hypotension is a late sign of shock in children, and, if not addressed expeditiously, will lead to cardiovascular collapse and possible death. Tachycardia and signs of end organ hypoperfusion, such as altered mental status, cool distal extremities, and decreased urine output, may be the primary clinical signs of shock in an injured child.

The focus of therapy for shock in an injured child should be on restoration and maintenance of adequate oxygen delivery and organ

perfusion. Hemodynamic monitoring of central venous pressure and direct arterial blood pressure, as well as cardiac output, may be necessary. In addition, clinical parameters such as base deficit, serum lactate, and measured creatinine clearance are useful indirect measures of adequate end organ perfusion and may have prognostic value.⁴⁶ Appropriate therapy of early shock resulting from trauma can alleviate the development of SIRS and multiple organ failure.

The tissue ischemia and hypoperfusion associated with shock result in alteration of cellular function due to oxygen and nutrient deficiency, eventually leading to activation of inflammatory mediators. A widely accepted model of SIRS and multiple organ failure in trauma patients is referred to as the “two-hit hypothesis.” The initial hit is the shock-resuscitation or ischemia-reperfusion phase, which activates neutrophils. The activated neutrophils are thought to be more susceptible to an exaggerated immune response following a secondary inflammatory stimulus (i.e., second hit).^{47,48} The immune response to trauma and shock remains the focus of active research and is discussed in greater detail throughout numerous chapters in this edition.

Renal Failure

Renal failure in pediatric trauma patients early in the hospital course is most often due to organ injury from the initial shock or from primary injury to the kidney, its vasculature, or urinary outflow tract. Anatomic reasons for renal insufficiency should be delineated by radiographic evaluation.

Renal failure that develops during the course of hospitalization is most commonly secondary to SIRS and multiple organ dysfunction syndrome. In addition, rhabdomyolysis, contrast nephropathy from imaging studies, or nephrotoxicity from medications may also contribute to renal failure. Rarely, abdominal compartment syndrome and/or renal vein thrombosis also can lead to renal failure.

Signs and symptoms of acute renal failure are due to electrolyte and acid-base derangements as well as volume overload. The first clinical features may be oliguria, hyperkalemia, and elevations in blood urea nitrogen (BUN) and creatinine. The laboratory evaluation of acute renal failure should include measurements of BUN, creatinine, electrolytes with phosphate, magnesium, and calcium, urinalysis, and urine electrolytes. Creatinine clearance should be measured to estimate glomerular filtration rate. Microscopy is necessary to differentiate hemoglobinuria or myoglobinuria from hematuria, and additional tests such as creatine phosphokinase can aid in the confirmation of crush injuries threatening renal function.

Prevention of acute renal failure includes appropriate resuscitation from shock and continued maintenance of cardiac output and organ perfusion. Additionally, minimizing and monitoring of nephrotoxic drugs is recommended. Attempts to prevent and treat acute ischemic or nephrotoxic renal injury with pharmacologic agents have mostly demonstrated no benefit. These agents include furosemide, mannitol, calcium channel blockers, and dopamine. Most of these studies have been performed in adults, and there are few dedicated studies in children.⁴⁹ While diuretic therapy may convert oliguric to nonoliguric acute renal failure, there is no evidence that patient outcome is improved. Prehydration and prophylaxis with theophylline or *N*-acetylcysteine has been shown to reduce the risk of contrast nephropathy and may be of benefit to children undergoing contrast scans who already have or are otherwise predisposed to develop renal failure.⁵⁰

Early institution of renal replacement therapy in the face of acute renal failure decreases morbidity.⁵¹ Peritoneal dialysis is a potential modality for infants and children (<10 kg), although trauma patients may have contraindications. Continuous venovenous hemofiltration dialysis (CVVHD) is a good choice in a high-acuity patient. CVVHD offers the benefit of constant and gentle manipulation and control of intravascular volume, electrolytes, dialyzable molecules, and serum osmolality.⁵² The development of regional anticoagulation with citrate-induced hypocalcemia has increased the efficacy and safety of CVVHD, especially in children at risk of bleeding from systemic anticoagulation.

Imaging

Owing to the complexities and specialized nature of pediatric radiology, an in-depth discussion is well beyond the scope of this chapter. However, there are two important points to consider in ordering radiology studies in the injured child, which will be discussed herein.

The most important issue is concern over ionizing radiation exposure. In the past 10 years, there has been a 700% increase in the number of CT scans performed, with nearly 11% of these occurring in children. The most common indications for the use of CT are evaluation of the trauma patient and diagnosing acute appendicitis.⁵³ This liberal use of CT scanning coupled with the fact that children have an estimated 10-fold increase in neoplastic potential at equivalent adult doses has led to growing concerns about the long-term deleterious effects of ionizing radiation in children. This has prompted a number of societies, including the American Pediatric Surgical Association (APSA) to issue a consensus statement regarding the use of ionizing radiation in children. These guidelines, known as ALARA (“as low as reasonably acceptable”), should be adhered to, particularly in children undergoing evaluation and treatment for traumatic injuries.^{54,55} The total amount of radiation should be reduced, repeat imaging should not routinely be used unless clinically essential, and the use of alternative imaging methods (e.g., ultrasound or MRI) should be considered. Many young children do not require the typical “trauma pan-scan” that is frequently utilized in adult trauma centers. Children should have CT imaging performed for suspected injuries based on injury mechanism and a thorough initial assessment. For example, many young children do not require chest CT following trauma. Information obtained from a routine chest x-ray is usually satisfactory, and a chest CT is rarely required to evaluate suspected great vessel injuries. There is mounting evidence that children treated in pediatric trauma centers have fewer imaging studies performed with no increase in missed injuries or mortality. In patients who require transfer to another hospital, CT scanning is often not indicated and should never result in delay of transfer to a dedicated trauma center.

Given the often subtle findings on children's x-rays studies, it is recommended that radiology studies be carefully reviewed with a pediatric radiologist. Incomplete bony ossification, open growth plates, and age-specific normal findings can often be misinterpreted as injury. Additionally, all films from transferring institutions should be re-reviewed with the pediatric radiologist to ensure all injuries are correctly cataloged. Discussion with the pediatric radiologist can be useful to determine the best methods to clearly delineate a particular injury. Finally, the pediatric radiologist can also help ensure that ALARA standards are being followed and can assist with ionizing radiation dose reduction. The pediatric radiologist is a valuable member of the pediatric trauma team.^{56,57}

Infectious Disease and Immunology

A child who sustains trauma is susceptible to infection via multiple mechanisms. The trauma itself may destroy the barriers of skin and mucosa, allowing both pathogenic and nonpathogenic organisms the opportunity to establish a clinical infection. In addition, significant immune dysfunction occurs following trauma, with abnormalities in cellular and humoral responses, as well as in macrophage and neutrophil function.⁵⁸⁻⁶⁰ Immune dysfunction can be categorized under two basic mechanisms: hyperactive, systemic, proinflammatory processes and depression of cell-mediated immunity. Hyperactive, pro-inflammatory responses may be ultimately deleterious to a child, leading to SIRS, multiple organ dysfunction syndrome, and death. Differences in the characteristics of immune dysfunction appear to be a function of the type of trauma (e.g., TBI, blunt trauma, burn injury) and appear to change over time, reflecting changes in the acute activation seen immediately after injury and subsequent evolution into immune suppression. Many of the abnormalities may be directly correlated with the severity of injury. Infections occurring within 5 to 7 days of admission are more likely to represent inoculation at the time of injury, whereas

infections occurring after the first week following trauma usually represent nosocomial pathogens.

Empiric antibiotic therapy of the pediatric trauma patient is usually reserved for open, potentially contaminated wounds. Trauma patients, in general, do not require empiric antibiotic therapy on admission to the ICU. No published data exist on the benefits or risks of empiric therapy for fungi or multiply resistant environmental bacteria in soil-contaminated injuries; therefore, extremely broad-spectrum antibiotic and antifungal agent prophylaxis is usually not recommended. Cultures obtained at the time of admission and surgical closure of open wounds can help the trauma team evaluate the child for infection later in the hospital course. Tetanus immunization should be considered in a child with devitalized, ischemic, and denervated tissues that have been inoculated by soil or with deep tissue injury by foreign objects that have been in contact with soil.

Nosocomial infections of indwelling vascular catheters, surgically implanted foreign bodies, the lung, the urinary tract, and injured tissues are all well recognized, with therapy targeted to the organisms prevalent in the ICU. Gram-stained exudates and cultures can provide information on the types and susceptibilities of the nosocomial pathogens causing infection. Providing sufficiently broad coverage empirically to achieve a high likelihood of success may both improve patient outcomes and decrease the emergence of certain antibiotic-resistant organisms. The definitive selection of antibiotics and a decision on the duration of therapy should be based on the isolated or suspected pathogens and the child's response to therapy. A poor response to broad-spectrum therapy despite the use of antimicrobial agents active against the isolated pathogens suggests either a hidden focus of infection, which may require further investigation and possible surgical intervention, or additional antibiotic-resistant pathogens not originally isolated. Lack of response to therapy may also be related to noninfectious causes of clinical instability. Therapy should not be continued indefinitely, because subsequent colonization and infection by antibiotic-resistant bacteria or yeast are likely to occur. Once antimicrobial therapy is discontinued, careful observation for relapse or recurrence of infection is essential.

Coagulopathies

Trauma is a potent activator of the inflammatory response, and a growing body of literature describes the relationship among inflammatory cytokines, endothelial function, and coagulation through cellular and molecular signaling.⁶¹ A severely injured child is at risk of impaired hemostasis as well as pathologic thrombosis.

Activation of the coagulation cascade is proportional to the stimulus. Local thrombus formation by a discrete injury is protective by inhibiting local bleeding, and pathologic thrombosis is normally impeded by anticoagulant mechanisms. Massive activation of the coagulation axis can overwhelm the counterbalancing mechanisms, leading to deep venous thrombosis locally or microvascular thrombosis systemically. The latter culminates in varying degrees of clotting factor consumption and pathologic and protective thrombolysis and may ultimately result in disseminated intravascular coagulopathy (DIC). The microangiopathic thrombosis of DIC can also contribute to hemolytic anemia, ARDS, and organ failure remote to the site of traumatic injury. The epidemiology of injuries in children puts them at increased risk of trauma-induced DIC because the brain and liver release strong procoagulant thromboplastins. Indeed, the likelihood of coagulopathy has an inverse relationship to the presenting GCS score.⁶² A recent paper showed that in children who meet clinical criteria for a head CT scan after trauma, a low plasma D-dimer strongly suggests the absence of significant brain injury.⁶³

Evaluation and treatment of physiologic derangements that promote bleeding are necessary in an injured child. Although definitive evaluation by laboratory assays may not be available immediately, early suspicion of coagulopathy based on clinical history, physical examination, and medical interventions may be lifesaving in a traumatically injured child. Even in the absence of a coagulopathy at presentation, it

is necessary to prevent iatrogenic coagulation disturbances. Dilutional coagulopathy can occur with the administration of as little as one unwarmed complete blood volume. After one to two blood volumes, platelets can be halved, and the activated partial thromboplastin time and prothrombin time can be doubled. In an injured child receiving blood products, coagulation studies should be sent early. As volume resuscitation continues, these studies should be checked frequently to refine blood product administration. Hypothermia may contribute to coagulopathy during resuscitation and must be aggressively prevented by various warming methods, including infusion-warming devices, increasing the resuscitation room temperature, and warm blankets.

If a patient has normal coagulation values but continues to bleed diffusely, an underlying bleeding diathesis should be considered. von Willebrand disease is the most common congenital bleeding disorder and has traditionally been assessed by a bedside bleeding time. However, uncertainty about the sensitivity, reliability, and predictive value of the bleeding time has led to a decline in its use. A platelet function assay, PFA-100, has been compared with bleeding time and is considered a superior screening test for primary hemostasis disorders. Thromboelastography is recommended to assess and treat the coagulation state of an actively bleeding trauma patient.⁶⁴

Recombinant factor VIIa can be used for controlling severe bleeding in blunt trauma patients. Several papers address its use in coagulopathic trauma patients requiring emergent craniotomy. It has been shown to reduce the size of intracranial hematomas and reduce need for transfusion with packed red blood cells (PRBC) and plasma.^{65,66} Thromboembolic complications following factor VIIa administration have been reported in adults and children, and, therefore, its use should be judicious.

Although the overall physiology of coagulation in children is nearly identical to that of adults, there are some special considerations in injured children. The neonate's relatively immature liver and initial nutritional needs increases the likelihood that vitamin K-dependent clotting factors will be decreased. Trauma resulting from abuse in infants and children frequently includes occult head injuries and the release of potent thromboplastins. Young children may also have an undiagnosed congenital bleeding disorder. Compared with adults, the relative health of the cardiopulmonary and renal systems allows children to tolerate significant hypovolemia and large-volume resuscitation that may result in a dilutional coagulopathy. The medical disorders and medications that can promote bleeding in adults also apply to children, although most are far less prevalent in the pediatric population.

In the ICU, patients are at an increased risk of pathologic thrombosis secondary to endothelial damage and indwelling central catheters. Traumatic and pharmacologic paralysis, in addition to bed rest, contributes to venous stasis. Although the risk of deep venous thrombosis and thromboembolic disease is lower in prepubertal children compared to adults, it is more prevalent than previously recognized.⁶⁷ Hypercoagulable states occur across the age spectrum, and children with nephrotic syndrome, inherited forms of thrombophilia, and some rheumatologic disorders are at increased risk of pathologic clot formation. Prophylaxis with low-dose heparin or automated venous compression stockings should be used in appropriate patients.

Nutrition

Nutritional support of critically injured children is extremely important and may improve outcomes in injuries such as TBI and burns. A major difference between adult and pediatric nutritional support is the fact that children have a requirement for maintenance of growth and development. Pediatric patients have lower energy stores and an approximately 50% higher resting basal metabolic rate compared to adults.

Similar to adult trauma patients, a state of hypermetabolism exists in critically ill pediatric patients and pediatric trauma patients. Critically ill pediatric patients often require increases in protein energy to compensate for the increased resting metabolic rate. The enteral route for nutritional support is preferable, and a growing body of research

has been performed demonstrating the benefits of enteral versus parenteral nutrition. In a recent meta-analysis, the benefits of enteral nutrition included lower risk of infection and reduction in hospital length of stay.⁶⁸ Other proposed benefits include preservation of intestinal mucosal integrity, with decreased bacterial translocation and a reduction in multiple organ failure. Enteral feeding is also more cost-effective than parenteral nutrition in pediatric patients.⁶⁹ When enteral feeding is not possible, it is best to support the patient with total parenteral nutrition.

Owing to impaired gastrointestinal (GI) motility in critically ill trauma patients, enteral feeding may be poorly tolerated. Gastric emptying is often delayed following severe head injury. Additionally, many of the medications used during treatment of traumatically injured patients may affect GI motility (including narcotics, benzodiazepines, barbiturates, and catecholamines) and can adversely affect feeding tolerance. Therefore, many patients with severe TBI may not tolerate full enteral nutrition. In these situations, “trickle” or low-volume feeds have been advocated to prevent intestinal mucosal atrophy.

Large gastric residual volume associated with lack of tolerance of gastric feeding may increase the incidence of aspiration pneumonia. Continuous gastric infusion of formula, addition of prokinetic agents, or transpyloric feeding may improve feeding tolerance. In some pediatric trauma patients, enteral feeding may not be realistic, and the most important action is to provide nutritional support as soon as possible, with the decision of enteral versus parenteral support individualized to the patient.

Sedation and Pain

Injured children commonly require analgesia and anxiolysis during therapy and management of various injuries. There are myriad drugs that can be safely used to provide appropriate levels of analgesia and anxiolysis in children.

In addition to providing pain relief and anxiolysis, sedatives and analgesics may reduce elevated ICP, facilitate mechanical ventilation, prevent shivering, provide anticonvulsant activity, and minimize long-term psychological trauma from untreated pain and stress.¹³ The importance of restoring and maintaining circulating intravascular volume before administering sedatives cannot be overstated, as children may be “surviving” on endogenous catecholamine release, thereby barely maintaining adequate blood pressure and tissue perfusion. Administration of even small doses of any sedative in this situation may precipitate cardiovascular collapse and cardiac arrest. Empiric treatment of presumed hypovolemia should precede administration of sedatives in an acutely injured child.

In the initial setting of evaluating an acutely injured child, small doses of narcotics such as fentanyl, given in incremental doses (0.5 µg/kg per dose, up to 1 to 2 µg/kg) titrated to effect, can be useful in both providing analgesia and allowing a more detailed examination. A child with painful injuries (e.g., fractures, multiple abrasions) is often more cooperative and allows a more thorough examination after receiving adequate analgesia. Concerns about masking the presence of intraabdominal injury are unfounded, as the cooperation achieved from the analgesia outweighs the difficulty in examining an agitated, screaming child who is experiencing acute pain. It is rarely necessary to administer benzodiazepines or other anxiolytic drugs in the acute setting of pediatric trauma, provided adequate analgesia is provided. In a mechanically ventilated patient, benzodiazepine (midazolam, diazepam, lorazepam) administration by intermittent dosing or by continuous infusion is commonly used to provide anxiolysis. Recently, infusion of dexmedetomidine has been used for sedation.

A variety of short-acting drugs can be used to provide sedation for endotracheal intubation. A detailed analysis of the advantages and disadvantages of these drugs is beyond the scope of this chapter. Sodium thiopental (4 to 6 mg/kg) is commonly used in a hemodynamically stable child in this setting because it is rapid acting (onset within 30 to 60 seconds) and can be used to treat elevated ICP. Further, sodium thiopental (1 to 2 mg/kg every 15 to 30 minutes) can be used

following successful intubation to maintain unconsciousness during transport to the ICU, operating room, or radiology department. The use of thiopental for sedation for radiographic procedures in a non-intubated, spontaneously breathing patient should be reserved for elective situations in fasting patients, and it should be administered by an anesthesiologist. Pentobarbital may be substituted for sodium thiopental.

Except for inducing general anesthesia, the use of propofol for critically injured children is controversial and is rarely necessary in the acute setting. A poorly defined syndrome of metabolic acidosis and myocardial failure has been reported after giving propofol by continuous infusion in the critical care setting. Nevertheless, many experienced pediatric intensivists use propofol for short intervals, especially during the weaning of narcotic-dependent children from mechanical ventilation.

Nonaccidental Trauma

Abuse is a common cause of traumatic injury in infants and young children.^{70,71} Nationally, it is estimated that approximately 1600 children died due to abuse or neglect in 2014, a rate of 2.13 per 100,000 children.⁷² Children younger than 12 months accounted for 43.7% of these fatalities, and 85% were younger than 4 years. Recognition of inflicted injury is important to ensure appropriate care, prevent recurrence of abuse, protect siblings, and comply with reporting mandates. A multidisciplinary team is optimal for treating children with inflicted injuries. The team should consist of a pediatric trauma surgeon, the treating staff, a medical social worker, and a child abuse pediatrician.

A delay in seeking care is common in children with abusive injuries. Injury history may be absent, incomplete, or inconsistent with physical findings or the developmental capability of the child. Domestic violence is common in families of abused children. Children with inflicted injuries that have more subtle findings and patients with intact families are more likely to be misdiagnosed as accidentally injured. This may have serious repercussions, including further injury and death.⁷³ Children with abusive injuries have worse outcomes than those with accidental injuries, with higher injury severity, mortality rates, and accumulated costs.⁷⁴ Having a high index of suspicion for inflicted trauma is critical in assessing an infant who presents with lethargy, apnea, cyanosis, mottling, poor perfusion, or seizures without an obvious history of trauma.

Evaluation of children with inflicted injury should reflect the occult nature of many abusive injuries. The constellation of subdural hematoma, traction-type metaphyseal (bucket-handle) fractures of long bones, posterior rib fractures, and retinal hemorrhages are characteristic of inflicted injuries in infants. Although TBI is the leading cause of morbidity and mortality in abused children, some head injuries may not be easily diagnosed clinically.⁷⁵ Therefore, a nonambulatory infant with any type of abusive injury should have CT or MRI studies of the brain. The sudden deceleration with forceful striking of the head against a surface is an important mechanism in inflicted brain injuries in children. Hypoxic-ischemic insults and other mechanisms also appear to play a role. Subdural hemorrhage, classically localized at the parieto-occipital convexity or posterior interhemispheric fissure, is the most consistent autopsy finding in abusive head trauma (AHT). Subdural hematoma results from rotational deceleration forces that cause shearing of bridging cortical veins. Retinal hemorrhages are present in the majority of children with inflicted injuries, but their absence does not rule out abuse. Infrequently, accidental head injuries may cause retinal hemorrhages.⁷⁶ Therefore, an evaluation by a pediatric ophthalmologist is recommended in all children with suspected AHT. A skeletal survey should be done in all children with serious injury due to abuse or suspected abuse. Screening for abdominal trauma is also important, either through imaging or laboratory studies. A psychosocial evaluation is critical in families of children with inflicted injuries to help support the family during a time of crisis and evaluate for other comorbid factors including domestic violence, substance abuse, and mental illness.

Rehabilitation

Once life-threatening conditions have been treated and the overall medical condition stabilized, the pediatric trauma patient should be assessed for the restoration of maximal functional independence. It is the role of the pediatric rehabilitation medicine team to identify, assess, and promote maximum restoration of physical, cognitive, and psychosocial functioning in each patient. Members of the rehabilitation team, including occupational therapists, physical therapists, speech therapists, social workers, and schoolteachers, provide their expertise in returning the patient to maximum independent function. As a first step, it is important to identify the patient's functional deficits and subsequent level of disability and handicap as they relate to the patient's home, community, and school settings.

The rehabilitation process should begin early in the patient's critical care stay, as physical and occupational modalities may limit the adverse physiologic effects of prolonged immobilization. For instance, muscles lose their flexibility and bulk with inactivity, resulting in diminished strength and endurance. Joints become stiff and contracted, and skin breaks down, resulting in pressure ulcers. Interventions include passive joint range of motion, isometric strengthening, and appropriate bed positioning. Orthotic devices, placed at joints (e.g., elbows and ankles) in a neutral position, limit contracture formation. Speech and occupational therapists can evaluate oral motor function to assess safe swallowing and feeding, decreasing the patient's risk of aspiration. The dietitian evaluates the patient's nutritional status, providing recommendations for appropriate diet and caloric intake. The social worker and child life specialist provide the patient and family members with emotional and educational support during the patient's acute critical care stabilization.

It is through the collaborative efforts of the pediatric trauma team and the pediatric rehabilitation team that the survivor of a pediatric trauma maximizes functional independence and can be successfully discharged home.

Brain Death and Organ Donation

Clinical guidelines for the determination of brain death were first published in 1987 by the American Academy of Pediatrics.⁷⁷ These guidelines were revised in 2011 by the American Academy of Pediatrics, the Child Neurology Society, and the Society of Critical Care Medicine and establish the minimum standards that must be met before brain death can be declared in children. These guidelines state that two examinations including apnea testing must be performed following achievement of physiologic stability and in the absence of confounding factors (e.g., hypothermia). These exams must be separated by an observation period depending on the child's age. For newborns up to 30 days of life, the period is 24 hours, while in infants and children 31 days to 18 years the period is 12 hours. Apnea testing should demonstrate no respiratory effort during the test and a final PaCO_2 20 mm Hg above baseline and more than 60 mm Hg. Ancillary studies (e.g., EEG or radionuclide cerebral blood flow) are not required or a substitute for neurologic exam. The guidelines allow for the use of ancillary studies under special, well-defined circumstances, and a second exam is still recommended.⁷⁸

Trauma patients represent a large percentage of those who are declared brain dead in a pediatric ICU and, therefore, represent a large pool of potential organ donors. There continues to be a wide gap between the number of organs available for transplantation and the number of patients requiring transplants, with more than 100,000 patients currently awaiting transplantation in the United States. Improvement in consent for organ donation is one way to decrease this gap. Despite widespread acceptance of and support for organ donation

among the general public, only 40% to 60% of families give consent for donation. Consent rates for donation are improved when the family understands the concept of brain death and when the understanding occurs before the request for donation (decoupling). In addition, the consent rate is maximized when the requester has specialized training or is a member of the organ procurement organization (OPO). In pediatric trauma patients, involvement of the attending physician in the request process may also have a beneficial effect on consent rates.⁷⁹

In an effort to increase organ donation, federal regulations were issued in 1998 governing how potential organ donors should be identified and approached.⁸⁰ All hospitals must have an agreement with an OPO and must notify the organization of patient deaths. The procurement organization then determines the patient's suitability for organ donation. In addition, the hospital must have an agreement with a tissue bank and eye bank to coordinate tissue and eye donation. The family of every potential donor must be informed of the option to donate organs or tissues.

KEY POINTS

1. Injury is the leading cause of death in childhood. Trauma systems and trauma centers improve outcomes in injured patients. Pediatric trauma centers improve outcomes in children, and this is especially evident in traumatic brain injury (TBI). Care by a multidisciplinary trauma team led by a pediatric trauma surgeon and pediatric intensive care specialist improves outcomes.
2. Children are initially evaluated and treated by the American College of Surgeons Advanced Trauma Life Support (ATLS®) algorithm. The priorities of evaluation and resuscitation are identical to adult trauma; however, children have unique physiologic and anatomic differences that must be taken into consideration during initial evaluation and treatment.
3. Nearly 3000 children aged 1 to 14 years die each year as a result of TBI. Primary injury occurs based on linear and rotational forces. Secondary injury occurs following impact and is considered to be preventable (e.g., hypoxia). Treatment strategies for TBI should be aggressive to prevent secondary injury. Survivors of TBI frequently have life-long morbidities.
4. Determining the mechanism of injury and understanding the unique physiologic and anatomic considerations in children allow the trauma team to predict the organ systems injured and direct evaluation to these areas. Understanding injury patterns allows for the trauma team to minimize radiation exposure in children, which should be kept at a minimum.
5. Nonaccidental trauma is a major cause of morbidity and mortality in children under 4 years of age. Trauma providers must be vigilant in detecting injuries that are inconsistent with the mechanism provided or the child's developmental age. Suspected abuse must be reported to state agencies and should be thoroughly investigated in a multidisciplinary manner with a pediatric trauma surgeon, medical social worker, and a child abuse pediatrician.

Transplantation is an increasingly utilized treatment option for patients with organ failure. In 2014, 27,737 organs were transplanted in the United States, with over 122,000 patients on the waiting list.¹ Despite advances in immunosuppression and postoperative management, utility of transplantation is nonetheless dependent on the number of available organs. The majority of donor organs are cadaveric, of which 90% are from brain-dead (BD) donors. Increasing the rate of donor registry participation and consent has the greatest impact on the number of available organs. However, approximately 20% to 30% organs are lost before procurement despite aggressive medical management after intent for donation has been made.¹ This statistic highlights the profound physiologic variations occurring at the time of brain death and the suboptimal quality of resuscitation because of various reasons.² An intensivist can have a profound impact on the number and quality of organs salvaged by understanding the physiology of brain death and strategies used by organ procurement organizations (OPO) to optimize transplantation success. Establishment of clear guidelines, resuscitation endpoints, and an intensivist-led team can increase organ recovery from BD donors.³

■ DECLARATION OF BRAIN DEATH

The initial process of organ donation requires heightened awareness of potential donors on the part of intensive care unit (ICU) team. Often, potential donors are excluded by caregivers based on notions of donor criteria or ethical concerns regarding the conflict of care. Members of a local OPO are trained specifically to interact with families regarding organ donation issues in such a manner that a caregiver and an OPO are not seen in mutual opposition. With the permission of the family, blood may be sampled to determine the suitability of a donor before brain death. If devastating, unsurvivable head injury is recognized in a potential donor, basic resuscitation may begin before the declaration of brain death. Once brain death is confirmed based on standard criteria (see Chapter 178), the ICU team should act quickly to stabilize the physiology of the donor and decrease the time to transplantation.

■ PHYSIOLOGY OF BRAIN DEATH

Brain injury resulting in herniation occurs after rostrocaudal progression of ischemia. Events leading to brain death include hypertension with bradycardia (Cushing response) as the pons becomes ischemic. Further involvement of the medulla creates unopposed sympathetic stimuli that trigger a catecholamine “storm.” This surge of catecholamines damages end organs by inducing both severe vasoconstriction and proinflammatory response. Spinal cord ischemia and loss of sympathetic denervation result in severe hypotension. This is exacerbated by simultaneous ischemia of the pituitary and hypothalamus and the loss of homeostatic control. These events occur in varying magnitude or velocity, thus making management even more difficult. The resulting physiology is characterized by hemodynamic instability along with various secondary complications listed in Figure 173-1.

■ INITIAL DONOR RESUSCITATION

Care of BD donors requires multiple modalities and frequent reassessment to ensure that resuscitation endpoints are met. Donors often have

associated traumatic injury and chronic health problems. Moreover, treatment strategies administered before brain death are often directed toward maintaining cerebral perfusion, often to the detriment of other organs. Post-declaration management focuses on reversing this state and preventing further organ damage.

Various organizations provide algorithms for the standard management of BD donors. Protocols may be organ or donor specific.^{4,5-7} The United Network for Organ Sharing (UNOS) has provided a sample standard pathway involving an initial workup and therapy (Fig. 173-2). Regional OPOs can develop their own protocol based on this pathway (Fig. 173-3). These algorithms focus on ongoing resuscitation and provide evidence-based therapy, as well as a platform for future research in the field, both nationally and within regional donor networks. Immediate goals include establishing baseline organ function and stabilizing organ physiology. If not already in place, a central venous catheter and arterial catheter are inserted. Blood, urine, and bronchial cultures are obtained, and baseline biochemical values and infectious titers are determined. Lungs and heart are evaluated by performing basic chest radiography, echocardiography, and bronchoscopy. Blood typing and crossmatch are performed, after which initial graft allocation efforts are initiated by an OPO coordinator.

Most OPOs use critical endpoints as donor management goals. These are used to maximize the number of organs that can be transplanted per donor. These physiologic goals are specific but are also fairly broad and similar to basic resuscitation. Typical goals are listed in Box 173-1. A UNOS study in the Southwest region of the United States found that meeting 7 of 9 goals significantly increased organs transplanted per donor.⁸ This was true for criteria met at the time of donation and at the time of consent. However, only approximately 15% of donors met these goals. This illustrates the importance of goal-directed care and timeliness of its implementation. Standard ICU protocols should also be employed to prevent complications. Gastrointestinal and deep vein thrombosis (DVT) prophylaxis should be continued appropriately, blood products administered for anemia or coagulopathy, aspiration precautions instituted, hypothermia avoided, and electrolytes and acidosis corrected. Standard insulin protocols should also be continued because donors can be profoundly hyperglycemic. Serum glucose level of <180 mg/dL is associated with higher organ yield per donor and is consistent with the current general ICU guidelines.⁹

■ ORGAN-SPECIFIC CONSIDERATIONS AND CONTROVERSIES

Cardiovascular

Cardiovascular management after brain death is important to maintain perfusion and preserve the heart for donation. Catecholamine surge during herniation induces considerable myocardial damage.¹⁰ Right ventricle strain commonly occurs after increased pulmonary capillary perfusion and pulmonary overflow injury from increased vascular resistance.¹¹ Contractility must be frequently reassessed and quantified by performing echocardiography because regional wall abnormalities often resolve before donation.

Initial resuscitation includes crystalloid administration guided by central venous pressure (CVP), pulmonary capillary wedge pressure,

FIGURE 173-1 ■ Complications after brain death. (Adapted from Smith M. Physiologic changes during brain stem death—lessons for management of the organ donor. *J Heart Lung Transplant* 2004;23:S217-22.)

BOX 173-1

Physiologic Endpoint Goals in a Potential Organ Donor

Mean arterial pressure: 60-100 mm Hg
 Central venous pressure: 4-10 mm Hg
 Left ventricular ejection fraction: >50%
 Use of ≤ 1 vasopressor at a low dose*
 Arterial blood gas pH: 7.3-7.45
 Urine output: 0.5-3 mL/kg/h
 Serum glucose level: <150 mg/dL
 Serum sodium level: 135-155 mEq/L
 PaO₂:FiO₂ ratio: >300

*Dopamine ≤ 10 $\mu\text{g/kg/min}$, neosynephrine ≤ 60 $\mu\text{g/kg/min}$, or norepinephrine ≤ 10 $\mu\text{g/kg/min}$. (Adapted from Malinoski DJ, et al. The impact of meeting donor management goals on the number of organs transplanted per donor: results from the United Network for Organ Sharing Region 5 prospective donor management goals study. *Crit Care Med* 2012;40(10):2773-80.)

or other noninvasive measures (most recently echocardiography) to assess volume status. After adequate volume loading, vasopressors are often required to maintain perfusion pressure. End organ perfusion should be monitored by measuring oxygen delivery or central venous oxygen saturation. Protocols based on traditional volume and vasopressor management have increased the number of heart donations in the past (Fig. 173-4).^{5,12}

Previously used vasopressors include dopamine, neosynephrine, epinephrine, norepinephrine, and vasopressin. The immunomodulatory function of catecholamines makes them attractive for managing a donor's proinflammatory condition.¹³ Dopamine is less favored because it may suppress anterior pituitary hormones and may induce tachyarrhythmias.¹⁴ Treatment with high levels of norepinephrine and epinephrine is associated with cardiac and kidney graft nonfunction.^{15,16} Vasopressin administration is ideal since it is depleted in the face of pituitary ischemia and can reduce the dose of catecholamines administered.¹⁷ Therefore, vasopressin is used more in hormone replacement therapy (HRT) than as a true vasopressor. Low-dose supplementation increases the rate of high-yield procurement (>4 organs per donor) and should be used as a part of donor resuscitation.¹⁸

Pulmonary

Like the heart, lung function in the donor is affected by physiologic changes associated with brain death. Pulmonary edema after brain death results from elevated afterload due to catecholamine surge combined with increased venous return and decreased left ventricular function.¹⁹ Sympathetic discharge also increases inflammation of the

lung parenchyma and capillaries, leading to edema and failure.²⁰ These effects are significant because pulmonary edema and inflammation reduce lung donation rates to less than 20%.²¹ Standard criteria for lung donation include a clear chest x-ray and PaO₂/FiO₂ ratio of >300.²² Once a suitable donor is identified, aggressive lung-specific management is performed.⁴ Most protocols involve the use of frequent chest physiotherapy and bronchoscopy, diuretics, strict aspiration precautions, empiric antibiotics, and steroids.²³ Lung recruitment maneuvers and frequent bronchoscopy increase oxygenation and lung utilization.²⁴ Lung protective strategies involving low tidal volumes and moderate positive end-expiratory pressure prevent further barotrauma.²⁵ For the donor population specifically, acute lung injury is more common in those treated with increased tidal volumes; therefore, sustained recruitment maneuvers should be used with caution.²⁶ Similarly, excessive oxygen administration should be avoided because it can induce inflammatory cascades and apoptosis.²⁷ Diuretics are administered to decrease CVP for decreasing alveolar-arterial oxygen gradient. However, restriction of CVP does not increase lung utilization. Therefore, diuretics are less frequently used at present.²⁸

Renal

BD donors are typically volume depleted secondary to aggressive mannitol use and diabetes insipidus. Strategies for preventing renal injury include avoidance of nephrotoxic agents and maintenance of hydration. Large volume administration improves kidney and liver graft function by correcting hypernatremia.¹⁵ In contrast, hypervolemia exerts deleterious effects by inducing right heart strain and lung dysfunction.

Crystalloids are primarily used for initial resuscitation. Some societies advocate the use of colloids such as albumin to prevent water accumulation in the lungs. However, limited data are available to support this.²³ Hypertonic saline may modulate inflammation and is beneficial for donor resuscitation. However, sodium levels should be monitored closely because this can worsen graft function.^{29,30}

Endocrine

One of the more debated aspects of donor management is the use of hormonal therapy. A donor develops a variable panhypopituitary state after ischemia.³¹ Administration of desmopressin as DDAVP treats the subsequent diabetes insipidus that can further complicate fluid management. Similarly, vasopressin helps with catecholamine function, as stated previously. Dysfunction of the anterior pituitary gland is less consistent, with the variable effects of hormones given to counteract the loss of corticotropin and thyroid-stimulating hormone.³²

Initial enthusiasm for HRT was based on nonrandomized data that showed increased organ yield after the administration of a hormone cocktail containing triiodothyronine (T_3), corticosteroids, insulin, and vasopressin.^{6,12,33,34} Therefore, hormone cocktails became a part of the UNOS protocol for managing cardiac donors. Using this protocol,

animal models demonstrated beneficial reduction in vasopressors when given HRT.³⁵ However, more rigorous examination has indicated that combination hormone therapy has not been universally supported. Criticism of HRT focuses primarily on the thyroid and steroid components of therapy, which will be examined more closely.

ADULT STANDARDIZED ORDERS Page 1 of 2

DA Donor # _____

Initiate only after approval by Donor Alliance Coordinator. All orders are STAT unless otherwise noted and will be ordered throughout donor management according to donor's physiological status.

Donor Alliance accepts Donor as of ____/____/____ :____ MST.

Treatment Orders

- ☐ 1. **DISCONTINUE ALL PREVIOUS MEDICATION ORDERS EXCEPT PRESSORS & ANTIBIOTICS.**
- ☐ 2. Weigh patient and measure height in inches (if not already done).
- ☐ 3. Monitor BP (Keep MAP >60, SBP >90), cardiac rhythm, pulse oximetry, CVP continuously. Document VS every hour and PRN.
- ☐ 4. Hourly I & O. Notify coordinator if UOP is < 0.5 ml/kg/hr or > 5 ml/kg/hr (<____ or ____>).
- ☐ 5. Maintain patient's temperature between 35.5-37.5° C (95.9°-99.5°F). Order warming or cooling devices as needed.
- ☐ 6. Turn/suction Q 2 hours and PRN (May use rotation bed if available).
- ☐ 7. OG/NG Tube to low intermittent wall suction with Q4 hour abdominal assessment.
- ☐ 8. Vent Settings: A/C FiO₂____ V_T____ RR____ PEEP____
☐ ABG on FiO₂ 100% x 1 after bronch, then titrate FiO₂ to maintain SaO₂ greater than 95%
- ☐ 9. CXR Q4 hours
☐ Do first CXR **after** bronch and have read STAT
- ☐ 10. Surgical consult for: ☐ Arterial line ☐ Central Line ☐ Lymph Node Removal
- ☐ 11. Flush eyes with NS every 2 hours & keep covered with NS moist gauze

Laboratory Orders

- ☐ 1. Type and cross for 4 (four) units of PRBC, prefer CMV Negative or Leukopore reduced. Have blood bank stay 4 (four) units ahead at all times.
- ☐ 2. **STAT** labs to include:

| | | | |
|---|--|-------------------------------------|--|
| <input type="checkbox"/> ABO Confirmation | <input type="checkbox"/> Liver Enzymes | <input type="checkbox"/> PT/PTT/INR | <input type="checkbox"/> Lipase |
| <input type="checkbox"/> Basic Metabolic Panel | <input type="checkbox"/> LDH | <input type="checkbox"/> Calcium | <input type="checkbox"/> Lactate |
| <input type="checkbox"/> CBC with Differential | <input type="checkbox"/> GGT | <input type="checkbox"/> iCa | <input type="checkbox"/> Sputum Gram Stain ONLY. NO culture |
| <input type="checkbox"/> UA with Micro | <input type="checkbox"/> Alk. Phos | <input type="checkbox"/> Mg | <input type="checkbox"/> Qualitative Urine Pregnancy test x1 |
| <input type="checkbox"/> CPK, CK/MB, Troponin I | <input type="checkbox"/> Amylase | <input type="checkbox"/> Phosphorus | |

Other Labs: _____

NOTE When ordering these tests, feel free to order the panels used by your hospital.

IV Fluid Orders:

- ☐ 1. Maintenance IV fluid: _____ at _____ ml/hr
- ☐ 2. Replace urine output IV ml for ml with _____ every hour
- ☐ 3. Bolus IV _____ ml of _____ over _____

Special Studies and Consults:

- ☐ **Cardiac Studies:**
 - ☐ STAT 12 lead EKG
 - ☐ 2D Echo with on-call physician interpretation (**Check with coordinator prior to ordering Echo**)
- ☐ **Pulmonary Consult** to "determine organ function for transplant." Consult to include:
 - ☐ STAT Bronchoscopy. (Please obtain two samples of bronchial lavage for testing)
- ☐ **Intensivist Consult** Indication: _____

Organ Recovery Coordinator Signature

Thyroid

Thyroid hormone replacement for donors was first examined in baboon studies in the late 1980s. Novitsky et al. observed the reversal of cardiac dysfunction after administering T₃.³¹ However, further animal studies could not demonstrate any benefit of T₃.³⁶ Similarly, numerous human studies were unable to show a beneficial effect of T₃ on cardiac function, inotropic support, or organ yield.^{37,38} Moreover, studies assessing thyroid hormone replacement with thyroxine (T₄) have yielded conflicting results.³⁹

Revised UNOS recommendations indicate that administration of vasopressin, diuretics, and steroids rather than thyroid hormones may increase organ yield.⁴⁰ A review and meta-analysis of thyroid administration in BD donors showed beneficial effect in all case series and retrospective reports but did not show any beneficial effect either alone or in combination with other hormone therapies in randomized controlled trials.⁴¹ Statistical issues complicate both retrospective and prospective reports. The strongest evidence thus far is provided by a retrospective review; however, this review examined a large data set of

over 66,000 donors.⁴² Multivariate analysis of this data set indicated a beneficial effect (increased organs procured per donor) of thyroid hormone administration independent of other factors. More importantly, thyroid hormone administration did not exert detrimental effects on graft survival. Therefore, use of thyroid hormones varies according to OPOs and to a donor's physiology.

Corticosteroids

The prominence of inflammatory mediators in BD donors plays a significant role in the management. The ischemic brain increases the levels of core inflammatory mediators that then cross the blood-brain barrier.⁴³ Increase in the levels of free radicals after

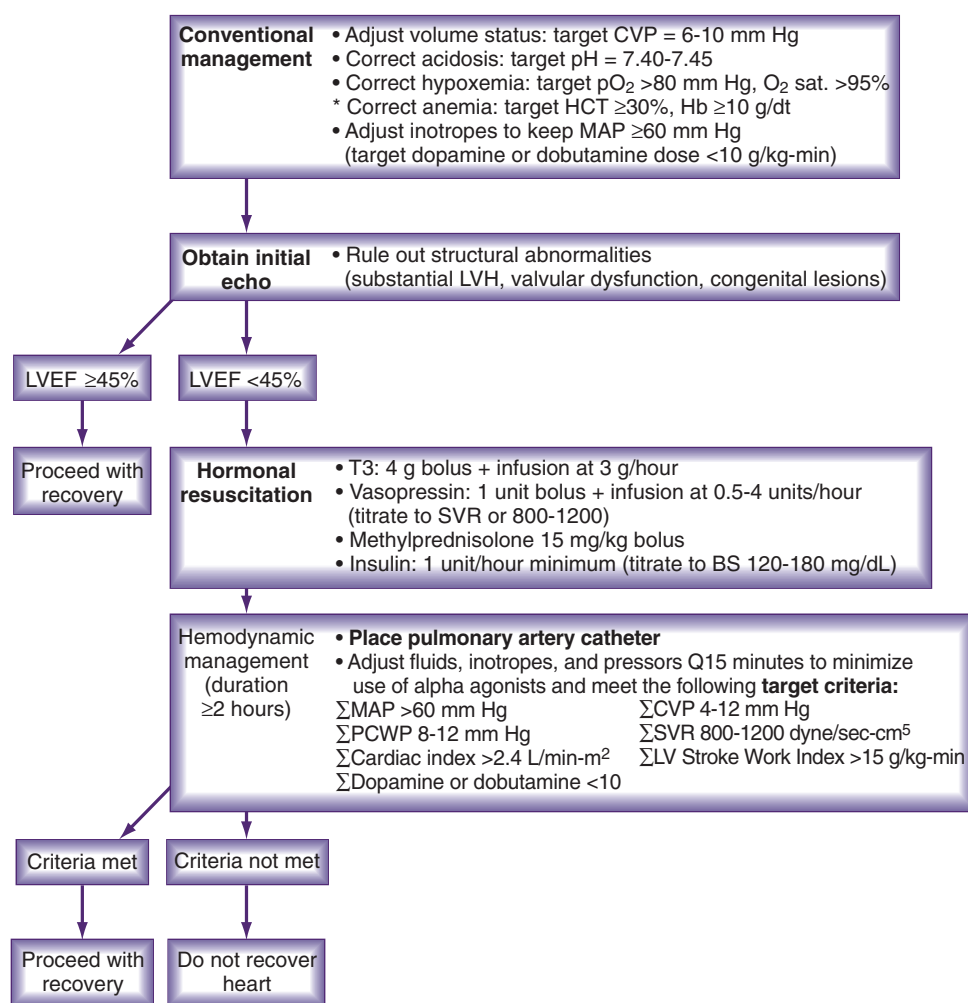

FIGURE 173-4 ■ Recommendations for cardiac donor management. (Adapted from Rosengard BR, Feng S, Alfrey EJ, et al. Report of the Crystal City meeting to maximize the use of organs recovered from the cadaver donor. Am J Transplant 2002;2:701-11.)

ischemia-reperfusion injury increases the local expression of adhesion molecules and influx of leukocytes (referred to as *passenger leukocytes*) in the transplanted organ.⁴⁴ These primed leukocytes can then affect graft rejection in the posttransplant period. Several studies have demonstrated increased rejection of the kidneys in BD donors compared with that in living-related, unrelated, or donation after cardiac death donors.^{45,46}

Corticosteroids are administered in donors to attenuate inflammatory response, to reduce rejection, and to increase organ yield. Methylprednisolone is typically given as a single bolus or a drip. Low doses of steroids in the form of hydrocortisone have also been used.⁴⁷ This decreased dose reduces hyperglycemia and need for insulin while maintaining comparable organ retrieval rates in donors receiving high-dose methylprednisolone. Few studies have evaluated steroid use in isolation from other hormonal therapies. The CORTICOME study showed no beneficial effect on graft recovery despite reducing the need for vasopressors in donors receiving hydrocortisone alone.⁴⁸ One can argue that reduction in vasopressor requirement can increase the number of organs that meet the criteria for donation. However, this needs to be studied in further studies. Similar to thyroid hormone administration, the overall quality of evidence for steroid use in BD donors is questionable. Most randomized trials on steroid administra-

tion have yielded neutral results, whereas observational studies have generally demonstrated improved hemodynamics and oxygenation status, increased organ yield, and improved graft function. Despite these mixed results, steroids are a widely utilized tool for organ donor resuscitation.

CONCLUSION

Donor management is unique in critical care in terms of perceived benefit versus risk: a life already lost has the potential to affect the lives of many others. Limited supply of cadaveric donor organs requires attentive pretransplant management to increase their availability and function. Maintenance of organs after brain death is extremely difficult because of hypothermia, acidosis, hypovolemia, pulmonary edema, cardiac arrhythmias, and profound hypotension. Important aspects of management include identification of potential donors, early hemodynamic stabilization with volume and vasopressor resuscitation, frequent reassessment of organ function and resuscitation endpoints, and provision of hormone replacement when indicated. Designated protocols can help focus on resuscitation and ensure the development of evidence-based guidelines. Although newer therapeutic modalities are promising, they require further research.

KEY POINTS

1. Brain death imparts profound changes to physiology including hemodynamic instability and loss of homeostatic control due to hypothalamic and pituitary ischemia.
2. Up to 30% of transplantable organs are lost during the management of the brain-dead donor.
3. Goal-directed care of the donor after declaration of brain death can increase organ yield.
4. The cornerstones of donor management include intravascular resuscitation, vasopressor administration, and hormone replacement therapy.

HISTORICAL PERSPECTIVE

The increasing gap between the number of organs available for transplantation and the number of patients listed for transplantation has become a rate-limiting step in reducing both wait times and wait list deaths in patients awaiting transplantation. Before the passage of the first United States brain death law in the state of Kansas in 1970,¹ donation after cardiac death (DCD, or donation after circulatory death) was the primary mode of organ donation in the United States. Donor death was determined according to traditional cardiopulmonary criteria—that is, absence of pulse and blood pressures without cardiac activity.

Early organ procurement strategies were relatively crude and variable, which in turn prolonged warm DCD ischemia time (time from donor circulatory arrest to cold perfusion) and resulted in poor outcomes.² Impact of the variability of circumstances surrounding donor death, and thus the duration of ischemic time, on DCD graft outcomes did not become apparent until experiences with organs donated after brain death (DBD) increased.

The need for diagnosing brain death was a culmination of critical care physicians' growing ability to maintain physiologic organ function in patients with little or no hope of neurologic recovery after central nervous system (CNS) insults. The concept was first introduced at a CIBA Foundation meeting in England in 1965 and was subsequently endorsed with formal diagnostic criteria by Harvard Medical School in 1968.^{1,3} A new debate was sparked over the precise definition and timing of death and the concept of futile care. Acceptance of this medically, philosophically, and legally novel concept of certifying death while maintaining perfusion in a potential donor to guarantee procurement with minimal warm ischemia time (WIT) and graft damage revolutionized transplantation. Because early experience with DBD organs showed superior outcomes, use of DCD organs declined and was subsequently abandoned.⁴

The success of DBD organs along with the refinements in medical and surgical techniques exponentially increased the number of transplants performed in the United States. The 1984 National Organ Transplant Act led to the formation of the United Network for Organ Sharing (UNOS), a nonprofit entity that provided a basis for standardizing organ procurement organizations (OPOs) throughout the United States, and the Organ Procurement and Transplantation Network (OPTN). Early national OPTN data showed that 10,794 deceased donor transplants were performed in 1988.⁵ Six years later, these numbers increased by nearly 50% to 15,210 transplants. Moreover, the number of lung grafts from deceased donors increased annually from 33 to 708.⁵ Intestinal transplantation also increased with the introduction of DBD donors. The first intestinal transplant was performed in 1990; by 1994, 96 patients with intestinal failure received intestinal transplants.⁵ Concomitant advances in critical care reduced mortality in patients with end-stage organ disease, thereby resulting in increasing wait lists and decreased attrition. This is referred to as the growing "gap" between organ supply and transplantation demand. For example, despite the increased number of transplant centers and utilization of living donors in 1995, only 33% of registrants waiting for kidney transplant underwent transplantation.⁵ However, the rate of transplantation decreased to 10% during 1998 to 2002.⁶

Moreover, the numbers of young and previously healthy DBD donors stagnated because of several statutory changes in areas of gun

control, automobile safety (airbags, seatbelts, and lowering of legal blood alcohol limits), and helmet use. This decreased traumatic fatalities and changed the face of DBD organ donors.⁷ The demographics of a typical DBD donor transitioned from a young healthy person who was rendered brain dead because of a devastating head trauma to an older person with medical problems who was rendered brain dead because of a neurovascular insult. This transformation eroded some benefit of using a DBD donor and prompted a search for other options.

Because the use of live donor organs has not kept pace with the growing deficit of organ donors, strategies such as regenerative medicine and gene/cellular therapy, mechanical devices and xenotransplantation (use of grafts derived from animal donors) for treating end organ diseases and organ replacement have been explored. However, these strategies are not ready to replace durable organ replacement. Further, the activity surrounding social and legislative approaches, including increased public awareness, donor registration activities, and interest in presumed consent (requiring individuals to opt out of organ donation to prevent consideration for donation at death), may have peaked because of cultural and philosophical objections. Therefore, transplantation is again being performed using organs procured from DCD donors.

In the early 1990s, the Maastricht German transplant group rekindled interest in DCD organs⁸ by showing equivalent long-term outcomes in recipients receiving both DCD and DBD renal transplants.⁹ DeVita highlighted that the University of Pittsburgh Medical Center (UPMC) introduced the nation's first institutional policy to permit and regulate DCD.¹⁰ The need for such a policy arose when several patients/families asked to participate in donation after previously electing withdrawal of life-sustaining treatment. This request fell outside the current parameters of donation policies and guidelines. The UPMC policy became the first concrete model to use cardiopulmonary criteria to determine death for organ procurement.¹¹ Moreover, this policy highlighted a milestone in the evolution of transplantation. Since then, DCD has been adopted by many OPOs and hospitals nationwide. By December 2006, OPTN bylaws required that all OPTN members have a DCD donor protocol in effect.¹¹ Moreover, The Joint Commission now requires that all accredited institutions develop and implement standardized DCD policies.¹²

After more than a decade of ongoing scrutiny surrounding ethical issues and outcome assessment, several key issues regarding DCD remain controversial in both the lay and medical communities. These include (1) criteria for identifying potential DCD donors, thus avoiding financial and emotional burden of "failed" DCD, (2) optimization of DCD donor management, and (3) standardization of DCD procurement protocols to ensure a successful multidisciplinary effort with reproducible results. These issues will be explored in this chapter after a brief discussion on the definition and current status of DCD.

IDENTIFICATION AND CATEGORIZATION OF POTENTIAL DONATION AFTER CARDIAC DEATH DONORS

Although seemingly straightforward, successful utilization of a DCD donor involves identification and classification of potential donors, appropriate diagnosis of death, compliance with local policy of

mandated wait time between death pronouncement and procurement, and familiarity with exclusion criteria for DCD.

The initial step in DCD organ transplantation is the recognition of potential donors with sufficient time to prepare and preserve optimal organ function before procurement. DCD is defined as organ procurement after the determination of death, which is characterized by an irreversible cessation of cardiopulmonary functions.¹³ Critical care physicians and OPO staff must be familiar with diagnoses and clinical circumstances that qualify a patient as a potential DCD donor. Candidates are patients in whom withdrawal of futile life-sustaining treatment is being planned. Because optimal preservation of organ function is facilitated by coordinated perimortem care, graft quality can be compromised in situations where a patient's wishes regarding organ donation are unknown or where DCD is not offered as an option until late. Organ suitability may decline while attempts are being made to educate staff and families. Moreover, a treating physician must ensure that for patients on life support, withdrawal of life support must be independent of the decision to donate organs. At present, an OPO is responsible for coordinating surgical recovery and for preserving and transporting organs and tissues.¹⁴ An OPO should be notified within 1 hour as soon as a patient's death is imminent from natural causes or withdrawal of life support.

The once popular practice of managing potential DCD donors by placing vascular and/or intraperitoneal catheters to infuse cold organ preservation solution before the availability of consent for procurement¹⁵ has now largely been abandoned. This practice stimulated contentious debate from both the medical and lay communities; moreover, unlike several European countries, no US state adopted this presumed consent into law.

Management of DCD donors is facilitated by a classification scheme developed by Maastricht group in 1994¹⁶ and revised in 2000.¹⁷ Maastricht categories define potential donors by circumstances under which cardiovascular death occurs. A distinction is made between donors whose cardiopulmonary failure is uncontrolled or emergent (categories 1, 2, 4, and 5) and those whose death according to cardiopulmonary criteria occurs in a controlled manner after withdrawing futile life-sustaining support (category 3). The revised Maastricht classification is outlined in Table 174-1. Recent initiatives in the northeast United States involve training prehospital personnel to rapidly converse with preconsented victims of unsuccessful resuscitation after cardiopulmonary arrest (category 2) to determine potential DCD donors.¹⁸ Category 3 donors constitute the majority of United States and European DCD donors.¹⁷ It is difficult to compare DCD outcomes according to Maastricht categories because few authors use this

classification when reporting DCD results. Therefore, for uniformity, the remainder of this chapter will focus on category 3 donors.

Category 3 standardization is outlined in Figure 174-1 (the UNOS Critical Pathway for DCD). Typical patients may have the following characteristics: absence of or hyperactive respiratory drive, lack of adequate respiratory muscle strength, and severe hypoxemia or inadequate circulation in the absence of treatment with inotropic or vasopressor drugs. These patients are usually supported using ventilators or mechanical circulatory assistance such as ventricular-assist devices (VAD) or intraaortic balloon pumps. These patients may have also experienced severe neurologic insults but may not have met brain death criteria. Conscious patients usually develop degenerative neuromuscular diseases or end-stage cardiopulmonary diseases and are often ventilator or VAD dependent. These patients or their families may decide to discontinue life-sustaining support and request their organs to be donated.

The other category of potential DCD donors includes patients with impending cardiopulmonary death, the timing of which is either predictable based on patient-/family-requested withdrawal of care or unpredictable because of premature cardiac arrest before withdrawal. Given the lack of perfusion in DCD donors, prompt identification of death is needed to minimize organ ischemia, especially if uncontrolled cardiac arrest occurs. Organ procurement from DCD donors under uncontrolled conditions is technically feasible but is not physiologically ideal because of the inherent ischemic insult.

Various modalities have been proposed to help physicians identify death based on the absence of cardiac sounds, pulse, respiration, and response to stimuli. Confirmatory tests such as intraarterial monitoring or Doppler studies recommended by the Institute of Medicine (IOM)¹⁹ can be used to expedite the confirmation of death; however, these tests are not widely accepted at present. A DCD work group assembled in 2006¹³ indicated that electrocardiographic silence was not required for determining death but was sufficient to show the absence of circulation.

However, there is no agreement on the observation time required to rule out spontaneous unassisted cardiopulmonary resuscitation or autoresuscitation. The DCD work group¹³ and the Society of Critical Care Medicine (SCCM)²⁰ recommend that potential donors should be observed for at least 2 minutes but not more than 5 minutes to ensure the absence of spontaneous circulation. These recommendations pertain to the period between the loss of circulation and declaration of death and not between the declaration of death and organ procurement. Fugate et al. identified variability among DCD protocols within the United States, particularly for defining the observation of potential donors to rule out autoresuscitation.²¹ Although most centers followed the 2-to-5-minute observation period, there was variability in the definition of the period starting either before or after declaration of death, thus implying a total of 10 minutes. A prospective study by Dhanani et al. on the timing of determination of death in DCD donors showed that the longest period of arterial blood pressure (BP) resumption after declaration of death was 89 seconds.²² Moreover, only 4 of 41 patients examined showed return of BP after cessation; however, this only lasted between 1 and 172 seconds. Given the variability and limited data on the duration of observation, specific guidelines for the precise minimal duration of irreversible circulation are warranted. At present, local protocols are used to stipulate the requirements of the determination of death and duration of observation time before organ procurement.

An important part of identifying potential DCD donors includes predicting the occurrence of rapid physiologic deterioration and death in less than 30 to 60 minutes (depending on the organ to be procured) after withdrawing life-sustaining treatment.¹³ Failure of a potential donor to progress to cardiac death within the prescribed time disqualifies the donor because of the extent of organ WIT. Factors such as age, comorbidities, and preterminal vasopressor requirement can be used as predictors; however, no strict criteria have been universally adopted.²³ Lewis et al. from the University of Wisconsin developed a tool that uses clinical parameters to predict the suitability of DCD candidates.²⁴ This

FIGURE 174-1, cont'd

resulted in the development of guidelines to predict the likelihood of circulatory death within 2 hours after withdrawing life support. Kaufman et al. proposed four readily obtainable clinical criteria: (1) requirement for vasopressors to support BP, (2) absence of primary brain injury, (3) history of mechanical ventilation for ≥ 6 days, and (4) respiratory rate of less than 20 breaths/minute (in the absence of mechanical ventilation).²⁵ They noted that presence of two or more of these indicators accurately predicted death within 60 minutes after withdrawing life-supporting treatments, with a sensitivity and specificity of 81% and 78%, respectively. Robust analysis of retrospective DCD data would enable intensivists and OPO staff to precisely identify potential DCD donors, help minimize financial impact on and resource drain from hospitals and donors that “fail to progress,” and prevent unnecessary stress and disappointment for families during a psychologically vulnerable time.

Familiarity with relative and absolute contraindications for DCD, some of which overlap those associated with DBD, is important. These include multiple-operated abdomen, active sepsis, active or recent

extracranial primary malignancy, and active hepatitis B infection. With regard to virologic status, OPOs are well versed in performing rapid serologic testing to rule out latent viral infections and should be involved as early as feasible to initiate testing.

CURRENT STATUS OF DONATION AFTER CARDIAC DEATH

Volume

UNOS disseminates US transplant-related data and has reported DCD statistics since 1994.⁵ Data are available on the UNOS website (www.unos.org) and in UNOS annual reports. The annual number of DCD donors increased steadily from the mid-1990s to the early 21st century (Table 174-2). In all, 42 DCD recoveries were performed in 1993, which represented <1% of the total recoveries in that year. In 2012, DCD recoveries showed a 12-fold increase of 12% of all organ procurements.⁵

TABLE 174-2

DCD, Donations after cardiac death.

Outcomes

Despite ethical controversies, the real barrier to the widespread acceptance of DCD graft utilization is the poor outcome observed in early DCD experiences. Suboptimal organ function characterized by primary nonfunction, delayed graft function (DGF), and/or abbreviated graft survival have traditionally threatened the success of DCD organs because of warm ischemic insult associated with cardiopulmonary arrest.¹⁰ Although these observations were valid at that time, they accumulated during early experiences with transplantation and were thus inherently confounded by era bias.

On a cellular level, DBD and DCD organs show different injury profiles. DBD is characterized by a surge in serum catecholamines because of brain death, which induces hypotension and subsequent organ hypoperfusion. Animal studies have shown that hemodynamic instability of DBD organs may be further exacerbated by inflammatory cytokines such as interleukin-1 (IL-1), IL-6, and IL-8 that directly affect renal grafts.²⁶ In vivo studies evaluating DCD kidney grafts have shown less upregulation of inflammatory markers²⁷ relative to that in DBD grafts; however, these studies showed that prolonged WIT induced alternative pathways of injury, primarily those related to hypoxia. Rosenberger et al. found that hypoxia-inducible factors were correlated with renal allograft ischemia time.²⁸ These results suggested that increased incidence of DGF with DCD grafts was associated with a hypoxia-specific (and in some cases potentially reversible) injury. The primary lesson from the early DCD era was that the metabolically active renal cortex, biliary epithelium, pulmonary alveoli, and pancreatic islets were sensitive to ischemia, with warm ischemic injury manifesting as acute tubular necrosis, ischemic-type biliary strictures (ITBS), pulmonary fibrosis, and impaired β -cell function, respectively, and that these manifestations were postulated to translate into and account for both poor initial graft function and long-term complications.^{29,30,31} However, contemporary outcomes for each organ have improved.

Kidneys

Recent data have shown equivalent outcomes for DCD vs. DBD grafts. Droupy et al. reported improved outcomes and showed that

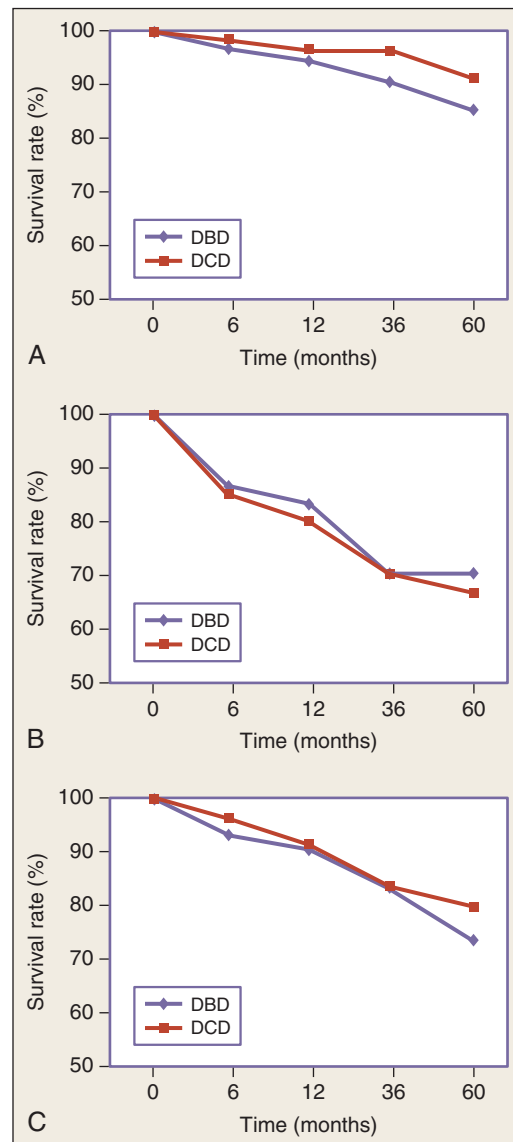

FIGURE 174-2 ■ (A) Ten-year graft survival after kidney transplant (donation after brain death vs. donation after cardiac death).³³ (B) Current outcomes after donation after cardiac death simultaneous pancreas-kidney transplant.³³ (C) Current outcomes after donation after cardiac death pancreas transplant.³³

intermediate- and long-term patient and graft survival in recipients of controlled DCD kidney grafts was equivalent or comparable to that of DBD.³² In addition, Droupy et al. reported that DCD and DBD renal grafts examined for 10 years showed equivalent survival despite higher initial incidence of DGF in the DCD cohort. Salvaggio et al. analyzed UNOS/OPTN data and showed similar results³³ (Fig. 174-2A). More recently, Summers et al. evaluated UK registry data and found no statistically significant difference in 5-year kidney graft survival in DCD vs. DBD recipients ($P = 0.97$).³⁴ Factors affecting graft function include donors' age of >60 years (compared to donors' age of <40 years) and prolonged cold ischemia time (CIT; >24 vs. <12 hours). These factors are associated with decreased survival of DCD and DBD grafts.³⁵ It is likely that the DGF rate among recipients of the two types of grafts is narrowed by the use of the pulsatile perfusion pump. Perfusion pumps, which are often used successfully with both standard and extended-criteria deceased donor kidney grafts, are increasingly being used with DCD kidney grafts. Lodhi et al. reported a decreased risk of

DGF associated with pulsatile perfusion compared to cold storage in recipients of DCD kidney grafts, which was similar to that observed in recipients of DBD kidney grafts.³⁶ A meta-analysis by Bathini et al. on the use of cold perfusion pumps suggested a trend of 1-year graft survival; however, the overall differences were not significant.³⁷ Other strategies to maximize graft function and minimize injury after transplanting DCD grafts include ex situ perfusion (ESP) and normothermic regional perfusion (NRP). NRP leverages the circulation of warm, oxygenated blood to reduce kidney injury. Valero et al. found that NRP considerably reduced PGNF and DGF³⁸; however, these findings should be confirmed by performing randomized clinical studies.

Pancreas

Much of the available outcome data on the transplantation of DCD pancreatic grafts are derived from cases of simultaneous pancreas-kidney (SPK) transplants. These data show that graft and patient survival rates in recipients of DCD pancreatic grafts are similar to those in recipients of DBD pancreatic grafts³³ (Fig. 174-2B). Transplantation of DCD pancreas alone grafts by using the same protocols as those used for DCD SPK grafts has provided favorable results³³ (Fig. 174-2C). Siskind et al. analyzed UNOS data from 1996 to 2012 and found no statistically significant differences in graft and patient survival rates at 1, 3, 10, and 15 years in recipients of DCD and DBD pancreatic grafts.³⁹

Liver

Early studies on recipients of DCD liver grafts have provided mixed results, with both graft and patient survival rates being significantly lower compared with those in recipients of DBD liver grafts.⁴⁰ In addition, these studies reported higher recipient morbidity and mortality rates.^{41,42} However, recent studies on the transplantation of DCD liver grafts have shown improved outcomes. Abt et al. reported intermediate- and long-term patient and graft survival in recipients of DCD liver grafts; however, this was less significant compared with that in recipients of other DCD grafts.⁴³ They also showed that 1- and 3-year patient survival rates of recipients of DCD liver grafts were similar to those of recipients of DBD liver grafts; however, graft survival rates of DCD liver grafts were lower.⁴³ (Table 174-3). Dubbeld et al. showed no statistically significant differences in 1- and 3-year patient and graft survival rates among recipients of DCD and DBD liver grafts when selected for donor age, serum transaminase levels, length of intensive care unit (ICU) stay, and vasopressor use. However, transplantation of DCD grafts was a risk factor for ITBS compared with that of DBD grafts ($P < 0.001$).⁴⁴ Moreover, survival of DCD liver grafts was more sensitive to WIT, thus justifying the procurement limit of 25-30 minutes after circulatory arrest (compared with up to 60 minutes for renal grafts). However, further studies should be performed to identify protocols for maximizing the quality of DCD liver grafts.

Lungs

Rapidly increasing utilization of DCD lung grafts, with improved outcomes, has encouraged clinicians to consider using these previously declined grafts.⁴⁵ Registry data from the Internal Society for Heart and

Lung Transplantation showed a 30-day mortality rate of <3% and 1-year survival rate of 89% that were not statistically different compared with those observed with DBD grafts.⁴⁶ Additional data from the United Kingdom Steering group for DCD lung transplants showed equivalent 1-year survival outcomes for DCD and DBD grafts ($P = 0.9$).⁴⁷ One evolving strategy for maximizing DCD graft function is ESP or extracorporeal perfusion that has been primarily studied in lung grafts, with some preliminary data on DCD grafts. ESP allows the assessment of graft through reassessment after the resolution of edema, via the evaluation of biochemical markers. Cypel et al. reported similar results for primary graft dysfunction, 30-day mortality, and 1-year survival with ESP compared to those with control lung grafts.⁴⁸ In all, 22 of 50 lung transplants were DCD grafts. This safe technique can help better identify the viability of DCD grafts and can improve transplantation outcomes.

Heart

Data describing DCD cardiac transplantation are scarce. To date, only five children have been documented to have received DCD grafts since 1996.⁵ Outcomes are inconclusive because of the limited number of recipients. DCD heart grafts are difficult to use because of unavoidable WIT. Nevertheless, DCD cardiac transplantation is technically feasible. The first human cardiac transplant, which was performed 40 years previously, was made possible by using a DCD heart that functioned well after a single electric shock.⁴⁹ A new era of DCD cardiac transplantation may begin with the advent of preconditioning therapy.

Because of the aforementioned OPTN and Joint Commission mandates, the number of OPOs facilitating DCD organ recoveries in a given year is increasing. In the last year reported, 56 of 58 OPOs facilitated at least one DCD organ procurement.⁵ The majority of DCD organs were kidneys (1593).⁵ The net effect of the current practice and improved outcomes has been to shift the paradigm of the binary cadaveric donor (DBD vs. DCD) to a spectrum of standard-to-extended criteria, with a DCD donor potentially falling along one of many points on that spectrum based on specific factors. The presence of distinct extended criteria factors in either a DBD or DCD graft may confer a higher risk of graft failure than an optimal DCD. The next logical question is whether increased volume of DCD procurements has affected transplant volumes and recipient outcomes or whether widespread adoption of DCD has shifted would-be DBD donors to DCD status without increasing transplant volume. This will be addressed in the final segment of this chapter.

PRINCIPLES OF DONATION AFTER CARDIAC DEATH DONOR MANAGEMENT

Because every organ from a DCD donor sustains some degree of unavoidable ischemic damage, several protective strategies to increase graft viability have been proposed. Interventions can be considered in premortem or intraoperative phases.

Premortem

1. Placement of large-bore arterial and venous catheters for perfusing cold preservation solution.¹⁴
2. Administration of systemic anticoagulants such as heparin (30,000 units) along with recombinant tissue plasminogen activator (50 mg)⁵⁰ or streptokinase⁵¹ to prevent vascular thrombosis during low flow state.
3. Administration of vasodilators such as phentolamine, chlorpromazine, or trifluoperazine to prevent agonal vasospasm induced by hypoxia and surging catecholamine levels.^{52,53}
4. Ischemic preconditioning: Brief preinsult ischemic challenges trigger protective mechanisms that allow compensatory tissue physiology at the time of cardiac arrest, which is suggested to be mediated by heat shock proteins.^{54,55} This effect has already been observed with phenylephrine in an animal model of non-heart-beating cardiac transplant.⁵⁶

TABLE 174-3

One- and Three-Year Outcomes of Donation After Cardiac Death and Donation After Brain Death Liver Transplantation⁴³

| TYPE OF GRAFT | YEAR AFTER TRANSPLANTATION | GRAFT SURVIVAL | PATIENT SURVIVAL |
|---------------|----------------------------|----------------|------------------|

FIGURE 174-3 ■ Donation after cardiac death monitoring form.

However, use of these premortem measures is limited because they are not a part of standard end-of-life care and because some authors suggest that these measures potentially hasten death.⁵⁷ The SCCM and IOM indicate that these medications and devices can be used as long as they do not cause any significant harm to the patient^{58,59} and as long as family consent is obtained wherever practical. That they are of no direct benefit to the patient is countered by the fact that they improve the likelihood that the patient's wish of organ donation will ultimately be realized.

Operative

The conduct of operative procedure is dictated by the tenets mentioned above. The procurement team is not physically present at the time of death, and recovery of organs is accomplished expeditiously with careful coordination of numerous personnel, equipment, and resources. To do so, the operative team prepares and drapes the patient upon arrival to the operating room (OR). The team outlines the necessary

instruments and maneuvers requested by OPO staff to ensure a seamless procedure. The team is then escorted from the OR and is notified by the OPO staff if the patient is pronounced within the prescribed time frame. After withdrawal life support and before incision, the OPO staff will complete a monitoring form (Fig. 174-3) that details minute-by-minute hemodynamic and oxygenation data.

Once the patient has been pronounced, the operative team returns gowned and gloved and infuses cold perfusate through a cannula or a standard terminal aortic cannula placed during the premortem phase after rapidly accessing the abdomen. Next, rapid but careful in situ cold dissection is performed because the potential for vascular injury increases without the benefit of pulsatile flow to assist the identification of aberrant anatomy. Finally, organs are packaged and implanted in the recipient as soon as possible to mitigate the added negative impact of CIT.

The two most common contingencies that the team must be prepared for are unexpected cardiac arrest while awaiting withdrawal of life support and failure to progress after withdrawal. Appropriate

intravenous access, a ventilator, and a special supply cart must be available and stocked with an oxygen tank, cardiac monitor, and adequate supply of sedatives and narcotics. The patient's wishes regarding resuscitation leading to donation must be determined from the patient or his or her family as early as possible.

DETERMINATION OF DEATH: THE EXACT SCIENTIFIC CONCEPT?

The 1980 Uniform Determination of Death Act (UDDA) established that death is determined when there is irreversible cessation of circulatory and respiratory functions.⁶⁰ Most often, death is declared based on the cessation of cardiac and pulmonary functions; however, required asystolic time is perhaps the single most contentious issue in the debate surrounding DCD.^{61,62} In simple words, the longer you wait, the more uncertainty there is about organs, and the shorter you wait, the more uncertainty there is on whether the person is dead.⁶³

As the limits of life-sustaining practices are expanded, medical professionals are encouraged to maintain focus with reference to the UDDA. The term *irreversible* can be interpreted as a shifting paradigm or as per Wilner, a concept that is subject to serial displacement by advancing clinical science. Wilner further highlighted that the question of death is thus reformulated to explore whether the morally relevant time of death is reached when death is certain despite the administration of all possible medical interventions or whether death is assured once all ethically permissible remedies have been utilized.⁶ Although consensus is yet to be reached on the time at which death is irreversible, it is logical that once a principled decision is made not to correct a loss of function, the loss becomes irreversible.⁶⁴

No investigator has documented autoresuscitation after >89 seconds of combined circulatory and respiratory arrest.^{22,65} However, the standard applied by most US hospitals ranges from 2- to 5-minute asystolic interval (pulselessness, apnea, and unresponsiveness). This broad standard is addressed by SCCM's statement that "there is no ethically or physiologically important distinction between the two minute observation period utilized by the University of Pittsburgh, the 5 minutes recommended by the IOM, and the 10 minutes."⁶⁶ Ostensibly, the standard does satisfy proponents of the waning possibility of autoresuscitation after 89 seconds of asystole and addresses ethical concerns raised by these proponents. Because of the paucity of empiric evidence, IOM

continues to encourage investigators to perform additional studies on this matter.

A final logistic issue in the determination of death is the management of patients who progress very slowly to be considered for donation. This occurs in approximately 5% to 10% potential donors.²³ Most programs disqualify donors from solid organ donation if cardiac activity is noted 60 minutes after withdrawal of life support because these donors do not meet the criteria for death because their organs would have sustained excessive warm ischemic injury.⁶⁷ Therefore, contingency plans should be devised so that these patients receive appropriate end-of-life care.

FINAL CONSIDERATIONS

Despite the success of DCD kidney, liver, and pancreatic grafts, several unmet challenges and questions remain regarding the transplantation of these grafts. These fall within the realms of medical and ethical concerns.

One area of likely future research concerns the real numeric advantage of using DCD grafts. Although the number of DCD grafts used in the United States has significantly increased, the overall number of transplants has not increased accordingly⁵ (Fig. 174-4). It is unclear as to what increase (if any) in available donor organs can be expected by promoting the utilization of DCD organs. Moreover, it is unclear whether the identification of DCD donors will convert would-be DBD donors to DCD donors. In addition, it is unclear whether the decrease in the number of wait-list deaths and the gap will shift the cost and burden from wait-list complications to posttransplant complications, with longer lengths of stay, increased readmissions, increased complexity of diagnostic evaluations and immunosuppressive drug regimens, and increased rate of recipient morbidity and mortality. These questions can be better answered once homogeneous, prospective data are collated.

One controversial topic involves the evaluation of pediatric patients. Koogler et al. reported that 28% of pediatric patients could qualify as DCD donors after withdrawing life support.⁶⁸ The authors estimated a 42% increase in organ donation if these patients were evaluated for DCD instead of only DBD. However, because a potential pediatric donor is physiologically extremely resilient, no tools are available at present to predict the likelihood of DCD in this patient population compared with that in the adult population.

FIGURE 174-4 ■ Total number of transplants in the United States performed using donation after brain death and donation after cardiac death grafts.

Furthermore, it is unclear how DCD will ethically affect the public's trust in the health care system and organ procurement and transplantation. On the recipient end, it is unclear whether the differential results associated with DBD versus DCD transplantation will mandate that a recipient be allowed to decline an organ donation based on the knowledge of physicians' concerns regarding the DCD process. As noted by the UPMC group and IOM, an emphasis on patients' and families' wishes is paramount for the success of any DCD program. The public will be guided by medical information. However, the practice of transplantation, which is donor driven, will be guided in a way that information is buttressed by open communication with the lay public.

Last, the concern of the lay public is that physicians caring for patients who are potential donors have shifted the focus of care from the dying patient and that there exists a latitude to violate the "dead donor rule" (comprising two complementary ideas: (1) the patient must be dead before organ procurement and (2) organ procurement must not be the cause of donor's death).⁶⁴ This concern in the public's mind may translate into fear that their likelihood of receiving aggressive life support will be compromised by consenting for organ donation. These misperceptions are particularly damaging when the overriding goal of the transplant community is to maintain and build public support of maximizing organ donation.

CONCLUSION

An Opportunity for Standardization

Appropriate management of DCD donors requires the integration of several fundamental principles for protecting the rights and interests of donors and for preventing the care of DCD organs from superseding the care of the dying patient. Debate arises in the paradox that can emerge from attempts to protect those interests while preserving the suitability of potential grafts. Hence, the role of an intensivist and/or palliative care physician (terminal care of patients and pronouncement of death) and managing OPO must be rigidly defined; the two factions must travel distinct paths to achieve their shared ultimate goal. Ozark summarizes this by stating "as a general rule two discussions—whether to forego life-sustaining therapy and whether to donate organs—must be made separately and on their own individual merit."⁶⁹ Ideally, discussion regarding the withdrawal of life-sustaining treatment should come first to prevent bias by the issue of transplantation.

The push for optimal palliative care is the hallmark of recent critical care management initiatives.^{21,70} Dying patients who also wish to be DCD donors present a special challenge because they require care that is not only comparable to that given to all dying patients but also sensitive to the concerns described above. The SCCM has offered recommendations specific to DCD.^{66,71} These guidelines supplemented by individual transplant center reports and UNOS pathway (Fig. 174-1) provide direction for intensivists caring for patients who wish to become DCD donors. It is vital that all health care providers involved in this process be comfortable with, and knowledgeable about, their specific role so that the patient's wishes can be respected.

Because pain relief is the single most important goal in palliative care in the final hours of life, there is a firm ethical, legal, and medical justification for using analgesics and anxiolytics in this scenario. Because some patients require higher doses than others, doses are given with the knowledge that unintended effects such as hypotension or respiratory depression may compromise organ viability. Therefore, it is critical that the interest of the dying patient is represented by a completely different entity than that responsible for representing the interests of the donor. If any question arises regarding the practitioner's ability to maintain an objective position, consultation from hospitals' palliative care and ethics teams should be sought.

In 2006, in the first criminal case against a transplant surgeon for the death of a donor, the defendant allegedly administered high doses of an analgesic and anxiolytic to a potential donor to hasten his death before organ procurement.⁶¹ Although the surgeon was acquitted, the case highlighted the potential legal ramifications of recovery teams'

involvement in the care of a dying patient. There is a consensus that "medications given to provide comfort are reasonable, even if they might hasten death" but "no medication whose purpose is to hasten death should be given to the patient."¹² Failure to attend to potential DCD donors' comfort in contemporary practice is considered suboptimal end-of-life care and should be managed only by the physician(s) caring for the patient.

The need for data collection during DCD evaluation is to standardize definitions of death without variability among hospitals or OPOs. For instance, the definition of the start of WIT remains variable, with some advocating a threshold of systolic BP of <80 mm Hg, some advocating a mean arterial pressure of 50 mm Hg, some advocating a systolic BP of <50 mm Hg, and some advocating a decrease in arterial oxygen saturation to <80%.⁴³ The lack of a universal definition renders comparison of outcomes between centers and organs difficult. Although the asystolic interval to be observed remains a matter of institutional policy, it is prudent to recommend the development of standardized criteria. Highly sensitive maneuvers used to document the absence of circulation, such as intraarterial pressure monitoring or echocardiography, may be helpful if a short asystolic interval is used.

Active debate exists regarding the optimal location of life-support withdrawal. Arguments for ICU withdrawal stem from proponents who prefer to provide families a normal setting to grieve, albeit briefly, at the bedside of their loved one. Others argue that effective and expedient progression to donor mode allows most successful procurement and can only occur in the operating room. At present, there is no standard protocol, and each facility is responsible for dictating a protocol for their institution.

Wiley noted that "the initial University of Pittsburgh policy called for the withdrawal of care to occur in the OR," which offered the advantage of minimizing the need to transport a patient after death and permitting the prepping and draping of the patient before death. This protocol was denounced for subjecting the patient to "a desolate, profanely 'high-tech' death surrounded by 'masked, gowned, and gloved strangers.'" The initial experience in Pittsburgh showed some truth to the proposition that presence of family at the patient's bedside at the time of death may be more important to the patient and his/her family than organ donation or location of death. When three of the first four families who were approached for DCD provided consent only when they were allowed to be physically present at the time of death, the Pittsburgh policy was changed to allow families into the OR or to move the withdrawal of care to the OR holding area. The area selected for the withdrawal of life support should allow family members to be present, accommodate necessary monitors and equipment, and be close enough to the OR to allow rapid transport immediately after death.⁷² Other programs followed in kind. According to the 2000 IOM report on DCD, a family's need to be present and involved in the dying process is generally widely cited in the development of hospital policies on the setting of withdrawal of life-supporting care.⁵⁹

The widening gap between suitable donors and patients in need of transplant continues to be the only issue that keeps solid-organ transplantation from achieving its complete potential in offering improved survival to patients with end-stage organ disease. Because current practices and outcomes have shifted the paradigm of binary cadaveric donor (DBD versus DCD) to a spectrum of standard criteria to extended criteria, the ultimate impact of the estimated unrealized annual 22,000 DCD donors⁷ on the actual number of organs available for transplantation will remain unclear until sufficient data are obtained under similar protocols. Although ethical questions regarding DCD persist, the process, which is increasingly practiced in a standardized manner, accommodates the needs of dying patients as well as those of patients awaiting transplantation, with improving success. Several organizations, including the SCCM,⁶⁶ UNOS,⁵ and IOM,⁵⁹ have endorsed the concept and issued relevant guidelines. As experience grows, attitudes change, and outcomes improve, DCD may have a significant impact on the number of organs available for transplantation and thus the quality of life of patients awaiting and receiving cadaveric organs.

KEY POINTS

1. Before **donation after brain death (DBD)**, procurement of organs from donors was referred to as non-heart-beating donation or **donation after cardiac death (DCD)**.
2. DCD organs are subjected to a variable duration of **warm ischemic time**, which negatively affects early and late graft function.
3. DCD organ procurements were reintroduced to expand donor pool and reduce wait times and wait-list deaths.
4. DCD lung, liver, kidney, and pancreas grafts are increasingly used, and outcomes have now improved with experience.
5. In the contemporary era of intensive care unit care and donor shortages, DCD may be the only effective method of organ donation for terminally ill patients who do not meet DBD criteria but wish to donate organs.

Nearly a quarter of the deaths in the United States occur in the intensive care unit (ICU),¹ and the majority of patients who die in the ICU have had life-sustaining measures limited or withdrawn.^{2,3} A decision to withhold or withdraw life support is often preceded by a family conference addressing the goals of care and treatment plans. Family conferences addressing the care of critically ill patients can be watershed events, clarifying the prognosis, defining goals of care, and providing support to family members and surrogate decision makers. Since most critically ill patients lack decisional capacity,⁴ families and other surrogates are often centrally involved in medical decision making. The care of most critically ill patients should involve an explicit discussion with surrogate decision makers about goals for care and treatment plans. Coping with a critically ill family member is challenging for surrogate decision makers, and many feel ill equipped to make decisions on behalf of their loved ones. Skilled communication by an interdisciplinary ICU team is associated with improved outcomes for patients and family members.⁵

Leading an effective family conference requires specific teachable clinical skills, and our aim is to present an evidence-based approach to communication with families of critically ill patients. This chapter first provides an introduction to medical decision making, with a particular emphasis on shared decision making. We will discuss a rationale for the importance of family conferences for all critically ill patients and address practical issues including the considerations of physician reimbursement and billing. We then present an evidence-based approach for family conferences, highlighting competencies, and protocols that have been developed to improve physician-family communication. Finally, we address the issues of cultural competency and spirituality as they relate to the care of critically ill patients and their families.

MEDICAL DECISION MAKING

Models of Medical Decision Making

Physician-patient or physician-surrogate involvement in decision making regarding life-sustaining treatments can be conceptualized on a spectrum, with parentalism at one end, autonomous decision making at the other, and shared decision making in between. Shared decision making describes a relationship in which information is passed from physician to patient or surrogate, and both parties share opinions about treatment choices before a decision is jointly reached. There is a consensus among multiple critical care societies in Europe and North America that shared decision making should be the default model for physician-patient and physician-surrogate decisions regarding continuing, withholding, or withdrawing life support in the ICU setting.^{6,7} Although most patient surrogates prefer a shared decision making approach,⁸ there is considerable heterogeneity among patients and families with regard to their desired level of decision control. In the interest of patient- and family-centered care, it is imperative to individualize one's approach. One study showed that American physicians use the full spectrum of decision-making models but do not routinely assess the surrogates' desired level of involvement in medical decision making. Rather than individualizing their approach to match surrogate preferences, individual physicians often have one approach that they use with all surrogates.⁹

Surrogate Decision Makers

The experience of family caregivers and surrogate decision makers is undeniably challenging. Surrogates struggle with emotional conflict and competing values, attempting to both honor the wishes of their loved one and promote harmony within the broader family.¹⁰ Caregivers are often under tremendous stress and have higher rates of psychological symptoms than the general public.¹¹ Specifically, the prevalence of anxiety and depression symptoms in family members of critically ill patients is remarkably high,^{5,12} and the symptoms of posttraumatic stress have been shown to be present in a majority of family members of critically ill patients. One study showed that 82% of family members who were asked to participate in medical decision making demonstrated symptoms of posttraumatic stress 90 days after patient discharge or death.¹³

In addition to the effective difficulty inherent in coping with a sick loved one, surrogate decision makers are asked to participate in complex medical decision making with which they may have very little prior experience. Communicating clearly about the goals of care and the withdrawal of life-sustaining interventions, as well as exploring patients' and families' wishes can contribute to the family support and satisfaction.¹⁴ Though clinicians may be familiar and comfortable with the fast pace of ICUs, the tempo of medical decision making can pose a particular challenge to surrogate decision makers. One study showed decreased family satisfaction associated with a longer ICU stay but increased satisfaction when the process of withdrawing life-sustaining interventions was prolonged,¹⁵ especially for patients with a longer ICU stay. This suggests that families may benefit from time to come to terms with medical decisions and their personal feelings of loss.

Substituted Judgment Versus Best Interest

Substituted judgment is upheld as the highest standard for surrogate decision makers.^{16,17} In the absence of an existing healthcare directive, clinicians ask that surrogate decision makers imagine what the patient would want were he or she able to participate actively in decision making. Despite widespread endorsement of the substituted judgment standard by the medical community, ethical and practical concerns have been raised,¹⁸ including the fact that patients frequently change their minds regarding medical decisions and preferences, making an estimation of a patient's wishes more difficult. This is especially true among patients who have not completed an advance directive.¹⁹⁻²¹ That said, though many patients evolve and change with regard to treatment preferences, most studies evaluating preference stability have shown that a majority maintain consistency in their wishes regarding medical decisions,^{22,23} particularly patients who have engaged in advance care planning and those who are seriously ill.²⁴

Some authors have raised concerns about the accuracy with which surrogate decision makers can predict what choices patients would make.¹⁸ A meta-analysis by Shalowitz et al.²⁵ found that surrogate decision makers were 68% accurate in their predictions regarding patient treatment preferences. In cases in which surrogates are inaccurate in substituted judgments, their stated preferences on behalf of the patient more closely represent their personal beliefs about end-of-life care.^{26,27} A majority of seriously ill and older patients prefer to defer complex decision making to their physicians and family rather than

having their advance directive strictly followed,²⁸ perhaps reflecting the understanding that it can be difficult to imagine what one's preferences might be given the many variables and unanticipated subjective experience of being critically ill.

Although there is significant variability in the amount of decision control desired by patients over their designated surrogates, the majority of patients prefer the implementation of a substituted judgment standard over the best interest standard.²⁹ Furthermore, there is heterogeneity in the factors weighed by surrogates in medical decision making, including substituted judgment, but also factors such as shared experiences with the patient and the personal values and preferences of the surrogate decision maker.^{30,31} Although this is a complex issue; substituted judgment should be a higher standard for decision making than the best interest standard.

Role of Advance Directives

The absence of an advance directive has been identified as a barrier to effective end-of-life care in the ICU setting,³² although significant and valid concerns have been raised as to their usefulness and relevance.³³ Advance directives were not widespread in the past: one small retrospective study of 61 patients found that one-third of those who died in the hospital entered with advance directives³⁴; however, others have described a much lower usage of between 5% and 11%.³⁵⁻³⁷ Although advance directives have not consistently been shown to change the type of care provided to dying patients,^{33,38} some studies have shown that the presence of an advance directive is associated with higher family assessment of the quality of the dying process for patients in the ICU,³⁹ greater use of hospice, improved communication,⁴⁰ an increased frequency of DNAR orders and better quality of life in the final week of life.⁴¹ Advance directives can be helpful to surrogate decision makers, lessening the burden involved in attempting to employ substituted judgment. Importantly, advance directives should be completed as part of a process of advance care planning that allows patients, their family members, and clinicians to explore the patient's values, goals, and preferences before documenting those preferences in an advance directive. Therefore, although more progress needs to be made in the role advance directives play in guiding end-of-life care, there is value in advance care planning for those patients who ultimately require critical care.

FAMILY CONFERENCES IN THE ICU

Importance of Family Conferences for All Critically Ill Patients

Robust communication among clinicians, nurses, and families of all critically ill patients is important, not only for families of patients who are imminently dying. Family members who felt that communication in the ICU was inadequate were at higher risk for posttraumatic stress disorder,¹³ even those with loved ones who survived their ICU stay. Furthermore, families of patients who survived their ICU stay are more likely to be dissatisfied with their ICU care with respect to domains, such as inclusion in decision making, communication, emotional support, and respect and compassion shown to family, as well as the consideration of family needs.⁴²

Practical and Logistic Considerations

Practical and logistic issues can shape the experience of surrogate decision makers in a critical care setting. Even physical space can have an important effect: a French study⁴³ found that family members of patients in private ICU rooms had a lower incidence of anxiety and depression symptoms compared with families of patients in multi-bed rooms. The same group also found that the absence of a dedicated room for family conferences was associated with increased anxiety symptoms among family members of critically ill patients.¹² Accessibil-

ity of physicians and the access to information also correlates with family satisfaction; inaccessibility has been correlated with conflicts related to prognosis,⁴⁴ suggesting that surrogate decision makers are more satisfied when clinicians are accessible and comprehensive in their communication.

Billing and Reimbursement

According to the guidelines from the Center for Medicare and Medicaid Services (CMS), U.S. physicians are permitted to bill for time spent consulting with surrogate decision makers either in person or by telephone. Furthermore, critical care clinicians are permitted to bill for critical care time for these discussions, provided that the patient is unable to participate in giving a history and/or making treatment decisions and the discussion is necessary for determining a treatment decision. Documentation for these conversations must include:

- The medically necessary treatment decisions for which the discussion was needed
- That the patient is unable to participate in giving history and/or making treatment decisions
- The necessity of the discussion and a summary of the medical records to support this necessity⁴⁵

Palliative care clinicians in the United States are recognized as an independent medical subspecialty by Medicare and, as such, can bill for their consultative services. Previously, prolonged service codes, frequently used in palliative care billing, required that additional time is spent "face-to-face" with the patient, meaning that time spent in meetings outside of the patient's room between clinicians and surrogate decision makers were not compensated. This changed in 2009, such that clinicians can now bill for prolonged service time spent charting, reviewing records, coordinating care with other clinicians, and importantly, meeting with surrogate decision makers outside of the patient's room.⁴⁶ Claims have been denied for palliative care specialists who are credentialed in the same specialty as the primary team physician, although these denials have been successfully appealed.⁴⁶ Of course, specifics regarding the billing for both critical care and palliative care specialists change over time, so clinicians will be well served to familiarize themselves with the most updated billing guidelines.

Evidence-Based Approach to Communication During Family Conferences

Patients and families are consistent in defining high-quality care in the ICU: timely, clear, and compassionate communication by clinicians; clinical decision making focused on patients' preferences; patient care maintaining comfort and dignity; and family care with open access and proximity to patients, interdisciplinary support in the intensive care unit, and bereavement care for families of patients who die.⁴⁷

Family conferences in the ICU setting are challenging, both for families and clinicians, but it is important to remember that the optimal skills to facilitate these sessions are both teachable and rooted in evidence. Utilizing these skills has the potential to improve outcomes for both patients and family members. Studies suggest that planning conferences early in the ICU stay is beneficial⁴⁸; family conferences held within the first 72 hours of ICU stay are associated with both decreased use of critical care resources among patients who die⁴⁹ and higher family assessments of the quality of death and dying.³⁹ Consistent communication across the medical team is also important; having a "preconference" prior to family meetings can ensure that families are given a consistent message.⁵⁰ As discussed earlier, having a dedicated room for family conferences is also associated with decreased anxiety among family members.¹²

It should come as no surprise that empathic communication is one of the cornerstones of leading an effective family conference. Focusing on listening to concerns of family members is particularly important. Most physicians spend a majority of time talking rather than listening when meeting with patients and families.⁵¹ Families have been shown to have higher levels of satisfaction and lower levels of perceived

TABLE 175-1 **Empathic Communication in Family Conferences**

| CATEGORY | SAMPLE STATEMENTS |
|--|--|
| Empathy about surrogate decision making | <i>Withholding or Withdrawing Life Support:</i> "This is really hard. There's not a right answer to this situation." <i>Determining Patient's Wishes:</i> "It is very difficult to be in a position like this where you have to put your own personal feelings aside and try to advocate for what you think he would want." <i>Fear of Making a Mistake:</i> "Many families in your situation worry they will look back and think, was there something we missed or something that could've been done earlier? In her case, I do not think that would be true." |
| Empathy about critical illness in a loved one | <i>Making Sense of the Disease Process:</i> "I know it is very important to try and understand as best as possible what happened to see if we can make sense of this." <i>Difficulty in Understanding Medical Information:</i> "This is a lot of information to take in. Please feel free to ask any questions you might have." <i>Physical Changes:</i> "It must be really hard to see your loved one like this." <i>Receiving Bad News:</i> "It is hard to understand why something bad just can happen to anyone, and when it is someone you love and care for, that is even more difficult." <i>Uncertainty:</i> "We pretty much have to take it day by day, and I know that this uncertainty makes things even more challenging." |
| Empathy about confronting death in a loved one | <i>Helplessness:</i> "It must be so difficult facing this loss and feeling like there is nothing you can do to change things." <i>Dying:</i> "Letting go is so difficult, but I believe you are doing her a great service by honoring her wishes at this time." |

conflict with clinicians who speak less and listen more.^{5,51} Family satisfaction is associated with the use of empathic statements, although this is a commonly missed opportunity: one study found that one-third of physicians in the ICU missed an opportunity to use empathic statements in family meetings.⁵² Table 175-1 summarizes categories and examples of empathic statements that can be used by clinicians in family conferences. The “Ask-Tell-Ask” approach advocated by Back et al.⁵³ (Table 175-2) is a helpful tool to assess baseline knowledge and evaluate the understanding of the information provided.

Assurances to families and surrogates that patients will not be abandoned before death and that efforts will be made to provide comfort and minimize suffering and statements of explicit support for medical decisions to either continue or withdraw life-sustaining interventions are associated with higher levels of family satisfaction.⁵⁴ The use of the VALUE mnemonic (value, acknowledge, listen, understand, and elicit, summarized in Table 175-3) to enhance clinician-family communication has been shown to improve mental health outcomes, including symptoms of depression, posttraumatic stress disorder, and anxiety in family members.⁵ Interestingly, family meetings using this tool were somewhat longer than the usual care meetings, and the percentage of family speech was also higher.

Discussing Prognosis

Despite the ethical responsibility to inform patients about prognosis, many clinicians are uncomfortable doing so and identify it as one of

TABLE 175-2 **“Ask, Tell, Ask” Approach to Discussing Difficult Communication Tasks**

| STEP | FUNCTION | SAMPLE PHRASES |
|--------|--|---|
| “Ask” | Ask the patient/patient surrogate to describe his/her understanding of his/her medical disease and prognosis. | “It would help me to know what your other doctors have told you about your father’s illness.” |
| “Tell” | Explain to the patient/patient surrogate, using simple, straightforward language, what you understand about his/her medical disease and prognosis. | “Unfortunately, it looks like your father’s illness is getting worse. With a disease as serious as his, 9 out of 10 patients will die within 1 month, and 1 out of 10 will be alive at 1 month. If your father survives this illness, it is very likely he will have significant disability and will likely be unable to live independently.” |
| “Ask” | Assess the patient’s/patient surrogate’s understanding. | “I want to make sure that I explained things clearly. Can you tell me, in your own words, what I just told you about your father’s illness?” |

TABLE 175-3 **VALUE Tool to Enhance Communication in the ICU**

| | |
|---|------------------------------------|
| V | Value family statements |
| A | Acknowledge family emotions |
| L | Listen to the family |
| U | Understand the patient as a person |
| E | Elicit family questions |

Adapted from Lautrette A, Darmon M, Megarbane B, Joly LM, Chevret S, Adrie C, et al. A communication strategy and brochure for relatives of patients dying in the ICU. *N Engl J Med* 2007;356:469-78.

the most difficult parts of their job.⁵⁵ Physicians in the ICU are more likely to discuss functional prognosis rather than the likelihood of survival. In one study,⁵⁶ clinicians did not discuss the survival prognosis in over one-third of family conferences in which the attending physician anticipated there would be a discussion of withholding or withdrawing life-sustaining interventions or discussing serious news. Since patients with a poor prognosis are more likely to decline life-sustaining treatments,^{57,58} discussion of the prognosis is critically important. Interestingly, surrogates rely upon far more than just the prognostic information provided to them by physicians,³¹ although most try to balance their assessment of the patient with the information provided by physicians in understanding prognosis. Surrogates also report that they understand and appreciate explanations of the uncertainty involved in prognostication,⁵⁹ although evidence suggests that the surrogates’ understanding of prognostic information is low, even when they rate the quality of prognostic communication highly.⁶⁰

Experts recommend framing prognosis numerically rather than using nonspecific terms (e.g., “1 in every 10 patients” rather than “uncommon” or “low risk”), framing prognosis both positively and negatively, and using consistent denominators when presenting rates of risk (e.g., “9 in every 10 patients with illnesses as severe as your father’s will die within 1 month,” and “1 in every 10 patients with illnesses as severe as your father’s will be alive in 1 month”).⁶¹ In addition, family members of critically ill patients report that they prefer numeric

estimates.⁶² Despite these recommendations and preferences of family members, a minority of critical care physicians use numeric estimates in discussing prognosis⁶³ and/or verify whether or not surrogate decision makers have understood the information provided using a method (e.g., “teach-back”).

Discussing Resuscitation

Most patients and their families have little personal experience with the critical care setting or with cardiopulmonary resuscitation (CPR). Knowledge of the probability of survival from CPR affects patients' choices about code status.⁵⁸ Unfortunately, many people base their assumptions on the likelihood of surviving CPR on information from the lay media, such as medical dramas on television, which dramatically overrepresent favorable resuscitation outcomes.^{64,65} Consensus guidelines have highlighted specific recommendations in discussing resuscitation with patients,⁶⁶ some of which may also help guide discussions with surrogate decision makers. The authors recommend that, among other events, admission to a critical care unit should serve as a trigger for a discussion of resuscitation preferences.

Another important recommendation is that the discussion be framed to review the overall goals of care rather than merely focusing on code status. It is also important to make a distinction between life-sustaining interventions and CPR, describe cardiac arrest and care plan options (including palliative care) in detail, offer quantitative information about the patient's likelihood of surviving to hospital discharge and longer term survival and functional status after resuscitation, offer a code status recommendation, and focus on trust and rapport building. In summary, CPR in the critical care setting is best addressed in the context of the greater goals of care, including a candid discussion of the likelihood of CPR survival and care alternatives, such as palliative and symptom-focused care.

Role of the Interdisciplinary Team

The complexity of critical care requires the involvement of a multidisciplinary team. However, conflicts between nurses and physicians are common,⁶⁷ particularly in the setting of end-of-life care, and are a source of significant work stress and burnout.⁶⁸⁻⁷⁰ Enhanced nurse-physician communication and collaboration have been associated with higher patient satisfaction^{71,72} and a lower incidence of anxiety and depression symptoms among families of critically ill patients,¹² as well as lower rates of burnout among nurses and physicians.^{68,69} Improving communication among the multiple clinicians within the ICU (i.e., physicians, nurses, respiratory therapists, social workers, and spiritual care providers) would undoubtedly improve not only workplace relationships and stress but also patient care and integrated communication with families and surrogate decision makers.⁷³

Palliative care specialists are an increasingly common hospital resource. Involvement of a multidisciplinary palliative care team is associated with increased patient satisfaction as well as decreased rates of ICU admission following hospital discharge and significant cost savings.⁷⁴

Role of Protocols and the Importance of Individualization

Many of the communication strategies that have shown efficacy were implemented using interventions designed with specific protocols. The tenets of patient-centered care affirm the importance of tailoring our

communication and interactions to specific patients and their families, rather than resorting to a scripted dialogue. However, given the many missed opportunities in the current level of communication with patients and surrogate decision makers in the critical care setting,⁷⁵ it is reasonable to look to communication approaches that have been rigorously developed and studied. Specific guidelines on communication techniques and strategies are intended as a starting point, and clinicians are encouraged to integrate these with their personal approach and authentic voice, as well as to adapt their approach to the individual patient or family.

Cultural Competence

Cultural considerations are fundamental in talking with families and surrogate decision makers from diverse backgrounds. Using language interpreters and cultural mediators is critical in facilitating communication with patients and families who speak different primary languages than clinicians. Ideally, the role of an interpreter transcends mere strict literal translation. Interpreters can assume the role of a cultural mediator, helping to interpret content bidirectionally. Even with the best cultural mediators, however, there are challenges inherent when language discordance exists. Interpretation of family conferences is a difficult process that can include critical errors, and it is difficult to provide emotional support for families in this circumstance.^{76,77} Implementing best practices (e.g., a preparatory meeting with interpreters before the clinical encounter, speaking slowly, confirming the patient's or family's understanding, and debriefing with the interpreter after the clinical encounter) can facilitate better communication and decrease the potential for misunderstandings.^{78,79}

Spiritual Issues

Spiritual needs figure prominently for many critically ill patients and their families, often explicitly or tacitly shaping decision making about medical care,⁸⁰ although these considerations are rarely discussed in family conferences.⁸¹ Increased family satisfaction has been associated with the assessment of spiritual needs.¹⁴ Exploring underlying spiritual beliefs and values can be extremely important in supporting families and toward finding common ground on medical decisions through shared decision making. In addressing spiritual concerns, clinicians should use caution in not stepping beyond one's role as a clinician or trying to resolve existential and spiritual questions⁸⁰; rather, the focus should be on assessing potential spiritual needs, then making referrals for spiritual care providers.⁸²

CONCLUSION

Conferences with families of critically ill patients are crucial and are one of the more formidable clinical challenges faced by critical care clinicians. Many approaches to medical decision making exist, and there is significant variability among patients and patient surrogates regarding their preferred role. There is a consensus that shared decision making should be the preferred approach of clinicians although care must be taken to assess the family's desired role in medical decision making and individualize one's approach accordingly. Having a critically ill family member and functioning as surrogate decision maker are incredibly challenging for families, but stress associated with this situation can be mitigated through integrated, thoughtful, and empathic communication by physicians and other members of the critical care team.

ANNOTATED REFERENCES

Two truisms of economics are that the supply of goods and services are finite and that supply is insufficient to meet all demands. The tension between supply and demand for food, water, energy, education, and other goods and services creates economies. All societies must determine how goods and services will be allocated to individuals. Although the term *rationing* connotes a specific process of allocation during circumstances of severe resource limitation (rationing coupons to allocate gasoline during World War II or one's daily ration of water on a life raft are examples of common use), *rationing* is a synonym for resource allocation. In this chapter, the terms will be used interchangeably.

Market-based economies allocate many resources on the basis of the ability to pay, but other strategies exist (Table 176-1).¹ In developed nations, some goods and services (e.g., healthcare and education) are treated differently from luxury goods and are allocated by society using criteria other than an individual's purchasing ability. Regardless of the strategy ultimately used to allocate medical goods and services, decisions to allocate medical resources are fundamentally identical to the decisions regarding the allocation of other resources. Since medical resources are finite, it is impossible to provide every effective treatment in every case where it might offer benefit, and the patient desires the care. Sometimes the decisions are *explicit*, with immediate repercussions—for example, the selection of one patient to receive a heart transplant when several might benefit from the solely available organ—or the decision to admit one patient to the last ICU bed when several patients are critically ill who would benefit from ICU admission. More frequently, the decisions are subtler and occur even when the supply of the therapy is not limited (e.g., the decisions to use cheaper antibiotics, sedative medication, or imaging modalities) when more expensive options might be beneficial. Finally, allocation decisions can be completely *implicit* and almost hidden. For example, the decision to build an ambulatory care clinic instead of adding ICU beds is an allocation decision with profound implications for the delivery of critical care services that is nearly hidden to the individual clinician and patient.

Although common and necessary, allocation decisions are stigmatized in medicine. Allocation decisions bring two major ethical principles into conflict: beneficence and justice. Beneficence guides clinicians to act solely in their patient's best interests while justice directs clinicians to act fairly.² This conflict may explain why euphemisms are frequently used to describe allocation decisions. For example, *triage*, *optimization*, *prioritization*, *cost-effective care*, and *basic health-care* all indicate some form of allocation decision.^{3,4,5} The purpose of this chapter is to explore these decisions in their many guises as they occur in critical care and to offer some guidance to the clinician for constructing processes for allocating resources in their ICU.

ALLOCATION VERSUS EVIDENCE-BASED MEDICINE

Decisions based solely on the evidence of efficacy of medical care are not rationing decisions. There is no medical obligation to provide and no societal obligation to pay for care that is harmful or ineffective. In fact, clinicians use special terms to describe interventions that fall into these categories including *futile*, *not the standard of care*, *medically inappropriate*, *wasteful*, or *experimental*.^{5,6} For example, an intensivist

who decides not to transfuse a critically ill patient with blood for a hematocrit of 27 is not rationing blood even though blood is an expensive and limited resource because there is evidence that this transfusion in many critically ill patients is of no benefit and may be harmful.⁷ The decision not to use human growth hormone, an expensive medication, in chronically critically patients is not a rationing decision because the available evidence suggests it is ineffective.⁸

Unfortunately, the assessments of benefit and harm are not as straightforward as the terms would suggest, and the line between effective, ineffective, and experimental often lies in the eyes of the individual clinician. Decision science has taught us that medical decision making is a complex process that frequently obscures the true rationale of the choice.⁹ In fact, judgments allegedly based solely on objective evidence of safety and benefit often incorporate a variety of subjective values and biases.¹⁰ These may include the value the clinician assigns to being wrong, the value assigned to trying to “rescue” a patient in imminent danger of death; the clinician's tolerance for uncertainty; the impact of the decision on the clinician's finances; biases about the patient's race, gender, functional status or age; and the cost or availability of the resource.¹¹ The transition from statements that summarize the evidence of benefit to recommendations that incorporate cost and other values is often very subtle. For example, the authors of a recent systematic review of colloid resuscitation in critical care conclude that “there is no evidence from randomized controlled trials that resuscitation with colloids reduces the risk of death compared to crystalloids in patients with trauma, burns, and the following surgery.”¹² This is a summary of the evidence of efficacy. Like all statements of evidence, it is impossible to prove the absence of efficacy of treatment. However, the authors conclude, “As colloids are not associated with an improvement in survival, and as they are more expensive than crystalloids, it is hard to see how their continued use in these patient types can be justified outside the context of randomized controlled trials.” The *Choosing Wisely* campaign, an initiative of the United States American Board of Internal Medicine, has carefully avoided the use of terms like *cost*, *value*, *cost-effective*, or *rationing* in favor of a framework of *evidence*, *safety*, and *medically necessary*.¹³ Avoiding treatments that lack demonstrated efficacy is certainly justified; however, it is notable that these efforts steadfastly avoid an explicit discussion of costs. For example, the critical care list of avoidable therapies in *Choosing Wisely* includes avoiding unnecessary blood transfusions and total parenteral nutrition in the first 7 days of critical illness but does not mention a long list of other unproven or harmful treatments in critical care (e.g., dopamine for septic shock or recruitment maneuvers in ARDS).¹⁴ Cost is listed as one criterion among five; the others include evidence, prevalence, relevance, and innovation. Fundamentally, what the authors are offering here is a cost-savings analysis without an explicit cost evaluation that may have been politically or socially unacceptable.

These examples show how assessments of cost can creep into recommendations for therapy even without an explicit assessment. Since clinicians and payers may be reluctant to admitting that they are incorporating cost or availability into the rationale for a decision, they may find decisions of futility or appropriateness less ethically problematic than rationing. In fact, these judgments may implicitly contain assessments of cost by incorporating cost into the definition. When is there sufficient evidence to move a treatment or diagnostic device from

experimental care to standard care? When is there sufficient evidence, absent evidence of outright harm, that treatment is ineffective as opposed to not yet of proven efficacy? These decisions are frequently made by consensus bodies using subjective or poorly characterized criteria. The amount of evidence will tend to be higher for treatments that are risky, expensive, and that lack any alternative. Conversely, the threshold for accepting a treatment as “standard” will be lower if it is inexpensive, safe, and offers the potential for the rescue of a patient in imminent threat of death. For example, consider the decision to elevate the head of the bed of mechanically ventilated patients to prevent ventilator-associated pneumonia. This is an inexpensive and safe treatment to offer patients. It would take less evidence to convince clinicians to use this treatment than to use kinetic beds or prophylactic topical antibiotics, which are more expensive and may raise safety issues. Therefore, the cost of an intervention may be incorporated into assessments of whether it is the standard of care.

These judgments are further complicated by the motivation of the decision maker. It would be difficult for an insurance company that is assessing whether a specific therapy is experimental or standard of care to be unbiased when its decisions affect its profits. Since medical decisions are so complex, and decisions in the ICU are further clouded by their immediacy and the illness of the patients, it is essential that clinicians understand their motivations and the evidence supporting their decisions and have a process in place for allocation.

| TABLE 176-1 Strategies for Allocating Resources | |
|---|---|
| PRINCIPLE | DEFINITION |
| Autocracy | To each according to the will of one |
| Democracy | To each according to the will of the majority |
| Equality | To each according to an equal share |
| Lottery | To each according to an equal chance |
| Capitalism | To each according to his or her ability to buy |
| Personal worth | To each according to his or her contribution to the community |
| Utilitarianism | To each so that the utility of the community is maximized |

■ ALLOCATION STRATEGIES

Given that an intervention is effective, clinicians will face decisions to allocate resources at the bedside. These decisions are usually separated into macroallocation decisions (involving groups of people and usually made at a managerial or health policy level) and microallocation decisions (made at the bedside and involving identifiable specific cases). A hospital’s decision not to hire additional ICU nurses is a macroallocation decision. A nurse manager’s decision to allocate a specific patient to share a nurse in the ICU rather than to receive 1:1 nursing is a microallocation decision. This chapter is primarily concerned with bedside allocation or microallocation decisions that clinicians make on a routine basis. There is an important interaction between micro- and macroallocation decisions since macroallocation decisions ultimately affect individuals (Table 176-2).

There are a number of approaches to allocating resources (see Table 176-1). While these are all feasible, they are not all equally ethical. The principles of equality, fairness, justice, and due process make some strategies less acceptable. The principle of utilitarianism directs resource allocation to maximize the “utility” or benefit of the most people for any given amount of resources. To the extent that “utility” can be measured by measuring patient outcomes, such as health-related quality of life and to the extent that we can estimate the effects of medical treatments on utilities, theoretically, we can calculate exactly which sets of medical treatments to pay for to maximize the benefit to the population. This is the fundamental principle underlying cost-effectiveness analysis, which is the quantitative embodiment of utilitarianism. Allocating medical resources through cost-effectiveness analyses has important limitations: (1) medical cost-effectiveness analyses cannot tell how much money to allocate to medical as opposed to other goods and services, just how to maximize health outcomes for any selected outlay of resources; (2) cost-effectiveness analysis methods may not fully account for some factors that society values (e.g., cost-effectiveness analysis routinely treats all human lives as equally valuable). However, society often places a very high value on saving identifiable lives in imminent danger of death and may not value additional years of life in the elderly as much as years of life in the young.¹⁵ Standard economic analyses may not value equal distribution as much as optimal distribution and, to this end, may discriminate in settings that society finds unacceptable¹⁶; and (3) a cost-effectiveness analysis is a mathematical technique that generates comparative outcomes for populations of patients. It is meaningless to speak of

| TABLE 176-2 Allocation Decisions at Different Levels | | | |
|--|--------------------------------|--|--|
| | DECISION MAKER | DECISION | RATIONALE |
| Not an allocation decision | Physician | Not to use human growth hormone in chronically critically ill patients | Evidence of harm in critically ill patients |
| | President of insurance company | Not to offer routine chest computed tomography screening for lung cancer | Lack of sufficient evidence of benefit |
| | Healthcare minister | Not to offer basic medical coverage to all people in the country | Endorses other goals than equal access to healthcare, for example, the importance of choice or the value of free market |
| Macroallocation decision | Physician | Not to admit routine postcoronary artery bypass patients to ICU | Limited ICU beds used for patients with more severe illness |
| | President of insurance company | Not to increase reimbursement for septic shock when new, expensive drug is approved | Hopes to limit cost of care for patients to increase profitability of insurance company |
| | Healthcare minister | To capitate reimbursement for hospital care | By providing single fee for all care, hopes to limit costs so that increased outpatient services can be provided |
| Microallocation decision | Physician | Decision not to admit a debilitated, elderly man with urosepsis to the ICU despite a request by the patient’s primary care physician | The intensivist’s deciding the patient was moribund and that the ICU’s resources could be used to reflect better on other patients |
| | President of insurance company | Denial of claim to pay for prostacyclin infusion for pulmonary hypertension. | A treatment specifically not covered by contractual arrangement with the insured patient |
| | Healthcare minister | Not applicable | Not applicable |

treatment as being “cost-effective” in an individual case in which the treatment either will or will not work.

The primary value of cost-effectiveness analyses as an allocation tool is the ability to compare various strategies.¹⁷ For example, one can compare the cost-effectiveness of captopril versus no captopril in survivors of myocardial infarction against using fluoxetine versus imipramine for major depression to decide whether to use captopril after a myocardial infarction, fluoxetine for depression, both, or neither. Cost-effectiveness analyses provide a ruler, regarding dollars per life-year or dollars per quality-adjusted life year (QALY) that allows these different treatments for different diseases to be compared. The crucial data that must be available to make these comparisons are information on the effect of the treatments on survival or health-related quality of life. Unfortunately, in critical care the number of treatments shown to improve survival or health-related quality of life is small. While we have data on strategies to reduce gastrointestinal bleeding, duration of mechanical ventilation, and catheter-related infections, none of these interventions has been shown to affect QALY.^{18–20} Therefore, the cost-effectiveness analyses for these interventions are expressed as dollars per gastrointestinal bleed prevented or similar.²¹ These ratios cannot be used to compare a treatment to prevent gastrointestinal bleeding with a treatment for myocardial infarction because the latter is expressed in dollars per QALY. Cost-effectiveness analyses with non-QALY denominators can be helpful in bedside rationing decisions when the intervention is shown to be equally or more effective and reduces cost. For example, special beds in the ICU have been shown both to prevent decubitus ulcers and to reduce the overall costs of care even when the cost of the bed is factored into the analysis. Therefore, the cost-effectiveness ratio (expressed in dollars per decubitus ulcer prevented) is a negative number.²² Non-QALY denominators are useless for comparative cost-effectiveness decisions in different diseases.

■ ILLUSORY COST SAVINGS

Since the earliest days of intensive care, technologic, workforce, and organizational innovations have been proposed as opportunities to reduce the exorbitant cost of critical care. In 1972 an optimistic author wrote, “[The] more promising approaches to cost reduction are all in an early stage of development now. Both deprofessionalization of the ICU by wider use of allied health personnel and the automation of therapeutic functions are just beginning to be applied.”²³ Despite the implementation of both of these measures, there is little evidence that cost increases in hospital- or ICU-based care have been curbed by technologic innovation. In fact, the opposite has occurred. This is not surprising since technologic innovation in other areas of healthcare, while often associated with better outcomes, is rarely a source of cost savings.

Cost analyses are problematic in medical care, and critical readers must be able to identify cost savings that are real and that will appear in their budgets, from savings in indirect costs that will be accrued elsewhere.²⁴ There are several common, but problematic, arguments about cost reduction in critical care: (1) that reduced ICU length of stay will reduce the cost of care in the ICU; (2) that reduced test ordering will reduce the cost of care in the ICU; and (3) that fewer admissions of futile-care patients will save money. It is important to recognize that not all calculated cost savings will be realized at the ICU or hospital level.

ICU costs are often inferred from the length of stay. For example, in a cost-effectiveness analysis of antibiotic-coated catheters, the authors assigned a cost of \$9738 to a catheter-related bloodstream infection.²⁵ Epidemiologic studies show that patients with catheter-related infections spend more time in the hospital, even after controlling for severity of illness.²⁶ The cost of a catheter-related infection is, in part, derived by simply multiplying the estimated number of extra days patients with catheter-related infections spend in the hospital times the cost (based on hospital charges) of a day in the ICU or ward. In fact, it is unknown if using antibiotic catheters shortens the ICU

length of stay since the randomized trials showing that antibiotic-coated catheters prevent infection were not sufficiently powered or did not show a reduction in mortality or length of stay.²⁰ Even if the antibiotic-coated catheters reduce the length of stay, money “saved” by reducing the length of stay is a different type of funds than the money spent in buying the catheters. By reducing the length of stay, the ICU will be able to care for more patients, but they will be sicker and more expensive patients.

Identifying treatments for specific conditions in the ICU that reduce overall costs, even if they have no effect on QALYs, is extremely useful to the intensivist allocating resources. Implementing economically dominant strategies is an easy allocation decision as they do not worsen patient outcomes and reduce costs. However, predicting the actual effect of any decision on the actual costs in an ICU or hospital is complex because each hospital performs cost accounting and budgeting in idiosyncratic ways. The effect of different payer mixes, contracts for nursing and respiratory therapist labor, allocation of indirect costs, and whether the ICU budget is fixed or grows with the number of patients served all influence whether allocation decisions accrue savings that can be appreciated at the ICU level. For example, the drug acquisition costs of once-daily medications are frequently higher than the medications administered more frequently. However, there are labor costs associated with administering medication more frequently that may offset the costs of the once-daily medication. Unfortunately, unless there is a sufficient workload reduction from changing to once-daily medication to fire a nurse, there will be little-realized savings. This is because labor costs are not infinitely scalable (e.g., if there is 15% less work to do, you may not be able to hire 15% less nursing hours). Patients who need 1:1 nursing care will continue to need this level of care regardless of whether the nurses are administering once-daily medication or not. It may be that changing medication routines improves care by more efficient use of nursing time, but this may not be reflected in a cost reduction. A reasonable criterion to consider for a proposed cost-saving intervention is whether it will reduce the amount of staff that need to be hired or whether it can reduce the acquisition costs for equipment or medication. If it will not, then cost savings is not likely to be realized in the ICU.

The cost estimate used in many cost-effectiveness analyses assumes that every day in the ICU costs the same. This is certainly true for what the hospital charges, from which these ICU costs were derived. However, this is not true in reality. The first few days in the hospital and ICU are far more expensive than the last days.²⁷ Patients are more likely to require active interventions and closer nursing care in the early days in the ICU. Clearly, interventions that reduce ICU length of stay cannot reduce early days in the ICU and simply eliminate later lower cost days. This is rarely accounted for in the cost analyses. This was validated at the national level as the United States healthcare costs peaked during a period when hospital inpatient days declined by 40%.²⁸ Therefore, the standard cost analyses overestimate cost savings likely to be realized by reducing the length of stay.

Reducing test ordering in the ICU has been offered as a technique for cost reduction. This is also a perfectly reasonable option to be offered on clinical grounds. Overtesting yields increased false positives that may lead to clinical complications in search of diseases that never existed. However, the actual cost reduction that will be seen at the ICU level by reducing test ordering is likely to be overestimated in a simple charge-based analysis of test ordering. The actual marginal cost of performing the 101st arterial blood gas test once the analyzer has already been purchased and the technician has been paid for the time to perform 100 arterial blood gases is minimal. If reductions in test ordering are of sufficient magnitude to staff the laboratory with fewer people or to forego purchasing new equipment, then significant cost reductions can be realized. In fact, depending on how indirect costs in the hospital are allocated, it is possible that a reduction in test ordering will place the clinical laboratory under considerable budgetary constraints. Fewer tests may reduce the amount of money that the laboratory director receives to cover staff costs that may not decrease in the same proportion as test ordering.

Patients may be admitted to the ICU even when they have a negligible chance of survival. It seems reasonable to assume that if these patients receive care outside the ICU that the resources that would have been expended without benefit in the ICU would be saved. On the surface, this appears to be a painless cost saving method that intensivists should look for. Unfortunately, a careful analysis of the potential savings from limiting care at the end of life shows that it is a relatively small amount of overall health care spending, that implementing these strategies may worsen overall health outcomes by affecting care that nonterminal patients receive, and that care would have to be withheld from young patients; some of whom would have had prolonged survival to achieve any savings.²⁹

STRATEGIES FOR BEDSIDE ALLOCATION OF RESOURCES IN THE ICU

Ultimately, allocation decisions will occur at the bedside in the ICU. A number of studies demonstrate that under settings of restricted access to ICU beds, physicians allocate these beds by the severity of illness. In these situations, the average severity of illness in the ICU increases as it does on the hospital ward.³⁰ Unfortunately, these decisions are also driven by arbitrary factors including age, gender, reimbursement, and physician power in the institution that can all affect access to ICU beds.³¹ It is important that clinicians plan in advance of these difficult decisions so that their deliberations are explicit, open, and guided by principles rather than ad hoc case-by-case decisions.

CASE 1: ADMISSION AND DISCHARGE CRITERIA

The Last ICU Bed

An intensivist is responsible for an eight-bed mixed medical-surgical ICU in a large community hospital that is currently full. Within minutes, she receives two calls, one from the emergency room where a 17-year-old has been admitted with diabetic ketoacidosis with severe acidosis and altered mental status but who is not intubated and one from a hospitalist who is seeing an 83-year-old severely demented patient on the ward who has developed acute respiratory failure and will soon require mechanical ventilation. There is only one open ICU bed, and none of the existing patients can be moved.

Perhaps the most difficult decision an ICU physician faces is the allocation of the ICU itself.³² Although this is a wrenching decision and has generated a literature devoted to triaging the last ICU bed, there is little evidence to indicate how frequently this occurs in actual practice. Mobile technology, flexible nursing staffing, and the availability of postanesthesia, emergency room, and step-down beds may make the ritual of the last ICU bed more a theoretic concern than an actual issue. The allocation of the last ICU bed feels particularly difficult because identifiable patients are affected by a very explicit decision. The decision is further complicated by the almost complete lack of data on the actual benefit of ICU care in specific conditions versus care on the ward. Few question that ICU outcomes are superior, but the relative benefit of ICU care and monitoring in specific conditions is unknown. Finally, the decisions must be made rapidly. A transplant committee also allocates a fixed resource, organs for transplantation; however, it can deliberate for weeks to prioritize recipients. The intensivist must allocate an ICU bed within minutes or hours.

The two most important steps in allocating the last ICU bed are to take steps to prevent it from occurring and to develop guidelines for managing the problem when it occurs. Strategies to prevent the last ICU bed phenomenon include staffing sufficiently for the anticipated volume of elective surgery or stopping planned surgery if sufficient ICU beds are not available. This includes arranging flexible nursing and monitoring options for caring for critically ill patients in other environments that are not physically in the ICU. Individual clinician biases and training can have a strong effect on the perception of the value of various life-sustaining treatments in the ICU.³³ To minimize the effect of these influences and maintain fair and equitable access to intensive

care services, admission and discharge criteria should be public, explicit, evidence-based, and fair. Public and explicit criteria allow all clinicians in the hospital to be aware of the policy. To the greatest extent possible, decisions should be evidence-based or, in the absence of evidence, appeal to national policy statements or local consensus.³⁴

Resolution

The intensivist went to the emergency room, evaluated the patient with diabetic ketoacidosis, placed arterial and central venous catheters, and arranged to have a nurse from the ICU float to the emergency room for the night to care for the patient in the emergency room. The patient with acute respiratory failure from the floor was intubated and admitted to the ICU's last bed.

CASE 2: TECHNOLOGY PURCHASE

Bedside Laboratory Testing

An intensivist is considering purchasing a point-of-care testing system to allow him to do arterial blood gases as well as certain chemistries and coagulation tests at the ICU bedside. The salesman has shown him data that says that the cost of performing the tests at the bedside is 40% less than the hospital laboratory charges, saving money for the patient and potentially making money for the ICU. Furthermore, the salesman presents data that the rapid turnaround of bedside testing leads to faster clinical decisions and a reduction in ICU stay by 1 day. The reduction in length of stay, argues the salesman, pays for the cost of the testing system in 18 months.

Arguments that increasing technology will ultimately lead to cost reductions have advanced since the beginning of intensive care.²³ When the purchase is being made primarily on the basis that it will be cost saving, or at worse, cost neutral, there are two important considerations for the intensivist to consider. Does the cost saving involve shifting fixed costs? Moreover, to what extent does the cost analysis rely on savings due to reduced nursing time or ICU days? Calculation of cost savings that fail to take into account the proper cost perspective that relies on shifting fixed costs and reduced labor time or ICU days to demonstrate cost savings may overestimate the actual cost savings.

None of the preceding discussion relates to the potential benefits of new technology. If clinicians feel that the evidence supports better patient outcomes from the technology and that it merits implementation regardless of economic consequences, then this is not a resource allocation decision. However, technologic innovation is rarely cheap, and the medical industry will usually try to persuade clinicians that the novel technology is not only better but that it also saves money.

When a clinical laboratory charges \$100 to perform an arterial blood gas, this is not because the reagents, analyzer rental, and 7 minutes of technician time to perform the test cost \$100. Most of the costs included in this charge reflect the fixed costs of maintaining a 24-hour-a-day, 7-day-per-week laboratory including quality controls, managerial costs, government reporting, and the laboratory's portion of janitorial and other services in the hospital. If the ICU switches to a point-of-care system and reduces the number of laboratory tests by 30%, none of these fixed costs will disappear. Unless the reduction in testing is so significant that the laboratory director can fire a technician or sell some machinery, the overall costs of running the laboratory will not be affected by the ICU's switch to point-of-care testing. If these fixed cost savings cannot be realized, then the laboratory director must still meet the budget demands of the laboratory in the face of reduced testing. The point-of-care appears to be less expensive because the fixed costs of maintaining an entire laboratory are not bundled into the purchase of the testing device, not because the tests themselves are fundamentally less expensive.

Resolution

The intensivist met with the director of the clinical laboratory. At this hospital, the budget of the laboratory was directly tied to the volume of

tests performed. If the ICU started to perform their own tests, the clinical laboratory would not be able to continue to provide its services. The ICU and laboratory directors instituted a quality improvement intervention to improve stat lab turnaround time with existing technology and decided not to purchase the point-of-care technology but to use those funds to buy some needed bedside mobilization equipment.

CONCLUSION

Allocation of resources in medicine is an unavoidable process. Clinicians do have control over whether these decisions are implicit or explicit, are made after open discourse or with no discussion, and whether the decisions are informed by available literature or not. Clinicians

in the ICU may, in fact, face fewer implicit allocation decisions than their colleagues in other areas because of the imminent risk of death in the ICU and society's value for protecting those lives. In fact, there is relatively little empiric evidence of how often intensive care services are allocated. The effect of different interventions on actual costs will vary depending on local factors including reimbursement and indirect cost allocation. Allocating ICU beds is the most challenging allocation decision most intensivists will face. The best time to handle these decisions is before they occur. Public, explicit triage and discharge criteria that are developed in collaboration with ICU users (e.g., emergency department, surgery, oncology) well in advance of the actual decisions are essential for fair and efficient use of intensive care resources.

KEY POINTS

1. Allocation of resources is synonymous with rationing and is an inevitable part of medical practice.
2. Clinicians often use a variety of euphemisms including triage, optimization, prioritization, and cost-effective care to obscure what are essentially allocation decisions.
3. Clinical decisions that are based solely on the evidence of risk, benefit, or patient utilities are not rationing decisions because they do not incorporate cost or availability.
4. Clinicians may implicitly incorporate cost or availability into their judgments of the evidence of risk or benefit in an attempt to avoid an explicit decision incorporating cost.
5. Allocation can occur at the macro level where decisions affect populations of patients or at the micro level where decisions affect individually identifiable patients.
6. Cost-effectiveness analysis is a quantitative methodology that applies a utilitarian approach to allocating resources to maximize the benefit to a population for any specified cost.
7. Cost is difficult to measure in complex endeavors like medical care.
8. Claims to reduce cost by reducing the length of stay, test ordering, or admission of patients who will likely die should be examined critically.

A scholarly analysis that brings rigor to terminology used loosely by medical professionals.

Hadorn DC. Setting health care priorities in Oregon. Cost-effectiveness meets the rule of rescue. *JAMA* 1991;265(17):2218-2225.

A rigorous application of cost-utility analysis fails to capture the value we place on saving identifiable lives. Whether this value is rational and whether it should be perpetuated is an important question; however, this analysis shows why rescue must be considered in any attempt to prioritize healthcare spending.

Marshall MF, Schwenzer KJ, Orsina M, Fletcher JC, Durbin C, Jr. Influence of political power, medical provincialism, and economic incentives on the rationing of surgical intensive care unit beds. *Crit Care Med* 1992;20(3):387-394.

An interesting and honest analysis of what happened when ICU beds were in scarce supply without an explicit plan for their allocation. The power and income generation of individual surgical attendings drove ICU allocation decisions.

Reinhardt UE. Spending more through "cost control": our obsessive quest to gut the hospital. *Health Aff (Millwood)* 1996;15(2):145-154.

A leading health economist challenges the notion that reducing hospital length of stay will reduce overall healthcare expenditures. Data from the United States show that marked reductions in hospital length of stay were not associated with a reduction in the rate of growth of medical expenditures. Instead, the author argues that costs were merely shifted from the hospital to other settings.

Luce JM, Rubenfeld GD. Can health care costs be reduced by limiting intensive care at the end of life? *Am J Respir Crit Care Med* 2002;165(6):750-754.

Challenges the notion that significant reductions in ICU costs can be achieved by limiting intensive care at the end of life. The authors argue that while there are many very good ethical and medical reasons not to continue care for patients in the ICU when their prognosis is grim, the cost savings from these decisions are not likely to be enormous.

FOUNDATIONS OF ETHICS IN CRITICAL CARE

All medical decisions are ideally made by the healthcare provider in tandem with the patient or a *surrogate decision maker* or a *healthcare proxy* speaking for the patient. The provider brings expertise in the science and practice of medicine, both knowledge and what Aristotle referred to as *phronesis*, or practical wisdom and both professional values and his or her own personal values. The patient or the surrogate decision maker when needed brings the values of the patient. Given the very nature of critical care medicine, the “best” treatment for a particular patient by a particular provider or team of providers cannot be known without the attention to these values. That many decisions in the care of critically ill patients are literally *life or death* questions coupled with the fact that critical care patients are infrequently able to speak for themselves at the time decisions are required combine to make the practice of critical care medicine particularly ethically challenging.

GOALS OF CARE AND MEDICAL DECISION MAKING

Surrogate Decision Making

Modern medicine has embraced the concept of shared decision making between patients and their physicians based on the principles of autonomy (for the patient) and beneficence and nonmaleficence (for the physician).^{1,2} This approach, as noted, is often more complicated in the intensive care unit (ICU). Whether decisions are made in the ICU to continue with aggressive and likely quite burdensome care or to withdraw care,³ there will often be some tension within the care team or between the care team and members of the patient's family (who may be conflicted themselves).⁴ In the ICU, as in other medical situations, this model of shared decision making affirms that patients have an ethical (and in many places, a legal) right to determine the goals of their medical care. Choosing which health-related goals to pursue for a patient who has temporarily or permanently lost decision-making capacity is an imperfect science, but an individual patient's wishes regarding care may have been made known in advance of a serious medical illness to the physician or to a specific preferred surrogate decision maker or to family or friends. The process by which patients, with or without the assistance and participation of their physicians, family members, or other close personal relations, plan for future medical care is called *advance care planning*.⁵ In general, the results of these deliberations are known as *advance directives*; defined broadly, they may be verbal or written and may be quite specific or very general. In this process, the patient may designate a preferred decision maker or healthcare proxy, may lay out general goals and values related to illness and medical treatment, and may determine what kind of care he or she would want in the settings of some anticipated situations. Subsequently, the advance directive helps direct medical care in the case of the patient's incapacity and comes into play only if the patient is unable to make his or her current wishes known.⁶ For example, a patient who awakens after a surgical procedure and is deemed to have decision-making *capacity* (see later) is asked outright about his or her wishes, and the advance directive is no longer necessary.

Advance directives have ethical authority in whatever form (including verbal), as long as the directive was promulgated within the requirements of valid informed decision making (see later) as a tool

for formally bringing the patient's values into consideration at a time when the patient is not capable of supplying them himself or herself. As noted, this method of approximating the patient's goals and values in times of serious illness is not perfect, and the reliability of a specific advance directive as “authentic representations of autonomous patient choices” is often suspected.⁷ Advance directives specific enough to guide the day-to-day clinical decision making in the ICU are rare; more commonly, the ICU physician is left to work with a surrogate to understand the priorities of the patient and then to make shared decisions for the patient. Even in situations in which the physician “knows what the patient would want,” the wise clinician will seek counsel from individuals who know the patient well to mitigate the risk of paternalism. Who then may and should act as surrogate? How should that surrogate make decisions for the ill patient?

In some cultures, physicians often turn to the “next of kin” for surrogate decision making. However, the legal status of surrogates varies from country to country, and in many jurisdictions this individual has no de facto legal or even ethical grounds for assuming this role. (However, in some cultures, religion, and legal traditions, serious decisions about life-sustaining care are not made by individuals but rightfully by the religious authority or clan leadership.) In a culture that favors individual autonomy, the best surrogate decision maker is the one chosen in advance by the patient.⁸ Often this individual comes from the patient's valued community; usually, this individual is a member of the patient's family or close social circle. In those jurisdictions in which such a hierarchy has been determined by law, a typical sequence might be (1) spouse, (2) eldest child, (3) next child, (4) parent, (5) sibling, and (6) close friend. Once a surrogate decision maker has been named, it may be helpful for the patient to clarify the role of the surrogate, from simply “tell the doctors what I want” to “use your judgment to make the best decision about my care.” Interestingly, when asked whether they would prefer that their advance directives be followed no matter what or that their care be discussed with their chosen surrogate, a majority of patients would cede authority to the surrogate along the lines of “use your judgment.”⁹

Even in situations where the appropriate decision maker is not the patient, it is helpful to have documented that the patient agrees with this approach. Similarly, some statement of the values to be used when deciding about medical treatment can be helpful.

Documentation of advance directives allows patients to make their values regarding and wishes for future care known, either formally or informally. As noted, these directives may also designate a specific surrogate decision maker who then has ethical and often legal standing to make medical decisions for the patient. In the absence of advance directives, the legally appointed surrogate or, in the absence of such a surrogate, those who know the patient well make decisions for the patient using substituted judgment based on his or her knowledge of the patient's health-related values. When no information is available about a patient's wishes or values, the decision makers should apply a “reasonable-person” or “best-interest” standard. In such cases, consultation with an ethics committee may be helpful.

Advance Directives

As noted, advance directives are formal or informal instructions to healthcare providers, family members, or others involved in a patient's care regarding treatment that may be required while the patient is unable to participate in medical decision making. The earliest form of

advance directive was the “living will.” Classically, the living will is restricted in terms of both scope and applicability. Living wills are usually reserved for patients with terminal illnesses and are typically restricted to statements about forgoing medical treatments that would “only prolong my dying”; they typically make explicit statements about the acceptability of discontinuing intravenous fluids and artificial nutrition if death is imminent and there is no significant hope for recovery. They usually do not provide instructions in the case of nonterminal illness and typically do not name a surrogate. A more generally useful legal document is the one that gives statutory authority to an individual to make medical decisions for a patient in the case of incapacity. This document is sometimes referred to as a *durable power of attorney for health care*. Similar to a durable power of attorney that provides legal decision-making authority for financial and other matters in the case of incapacity, this document provides legal standing to a named surrogate with regard to healthcare decisions. These documents typically provide an opportunity for an individual to give general information about healthcare preferences in a variety of situations. Some also provide an opportunity for the person to make a statement about the quality of life and the kind of life that would and would not be worth living. Preferences for organ donation, wishes for spiritual care, and even funeral arrangements are sometimes included.

Additionally, a number of advisory documents have been developed, including “values histories” and the medical directive developed by Linda and Ezekiel Emanuel.¹⁰ These documents may present a series of increasingly dire scenarios and ask about overall preferences (“do everything possible to prolong life,” “continue aggressive care but reevaluate often,” “keep me comfortable, but do not provide care that prolongs my life”), or they may ask more general questions about what makes the person’s life “worth living.” It is hoped that this information will be helpful to a surrogate who must decide whether to continue supportive care in the case of irreversible injury or damage or even to continue disease-oriented care in the case of critical illness and impaired decision-making capacity.

For a variety of reasons, advance directives have not achieved wide popularity. When they exist, they are often not specific enough to provide meaningful guidance.¹¹ Even when a detailed directive exists, questions often remain about whether the individual was adequately informed and, in some cases, whether the individual had decisional capacity at the time. For example, a patient’s advance directive says that she would never want to be on life support, but when she is asked about mechanical ventilation in the case of reversible respiratory failure from pneumonia, she says of course she would want that. Thus, following a legally executed advance directive without verifying what was meant by the patient and whether the written wishes apply to the current illness can be quite problematic. It could in fact result in a preventable death in a patient who, with proper education, would wish to be treated.

A more limited form of advance directive, known as a *code status*, is frequently sought on admission to the hospital. A code status is an advance directive that is specifically limited to a patient’s (or surrogate’s) preferences regarding cardiopulmonary resuscitation (CPR) and other measures in the event of a cardiopulmonary arrest. In many hospitals and other healthcare institutions, as a matter of policy, any patient who suffers a cardiac arrest is treated with interventions designed to attempt to reverse the life-threatening derangement, including CPR, electrical defibrillation, and intubation and mechanical ventilatory support. Because a patient who suffers a cardiopulmonary arrest will die in a very short time without interventions, the discussion about code status is as much about how a patient wishes to die, as it is about whether he or she wishes to live. Tomlinson and Brody distinguished three distinct rationales for a do-not-resuscitate (DNR) status¹²: (1) CPR has such a low likelihood of producing the desired outcome that it is effectively “futile,” (2) there would be an unacceptable quality of life after CPR, and (3) there is already an unacceptable quality of life, and cardiopulmonary arrest would be a welcome deliverance. While often conflated with wishes for treatment of a variety of current or future medical conditions, a decision about CPR may not

give much useful information about a patient’s preferences regarding other aspects of his or her illness. A patient may choose aggressive disease-oriented measures well into a severe illness but still choose to forgo resuscitation in the event of an arrest. This approach may be voiced in a statement such as, “I want to fight this thing with all I have, but when it is my time, I want to go quickly without suffering.” Such a statement would be an opportunity to address resuscitation status, in addition to addressing overall goals of care (see later).

Many ICU patients who are actively receiving intensive disease-oriented care have a DNR code status. Such a directive may save surrogates and family members from the emotionally difficult task of removing life-supporting care. A patient’s acceptance of DNR status may signify acceptance of the limits of medical science; refusal of DNR status in the setting of progressive irreversible illness may be an indication that the patient has an incomplete and perhaps unrealistic understanding of the illness. Further discussion addressing knowledge deficits or unspoken fears may increase the likelihood that the patient’s true wishes will be followed.

There are a number of common errors that may occur when discussing the code status. The first is failure to convey accurate information about the likelihood of success after an attempt at resuscitation. Many patients have an unrealistic impression of the utility of this intervention.¹³ Another type of error is failure to address postresuscitation issues, when caregivers mistakenly assume that “do everything in the case of a cardiopulmonary arrest” also means the patient wishes the care team to continue to “do everything” afterward. Patients who undergo CPR will most likely be incapacitated for at least a period after the resuscitation, even in the best scenarios. A third type of error is to not take the opportunity to identify a preferred surrogate decision maker, given the significant risk of temporary or even permanent brain injury after the attempt at resuscitation.

Any discussion of advance directives should attempt to answer at least three questions: (1) In the event of a cardiac arrest, do you want the healthcare team to attempt resuscitation? (2) If you become incapacitated, who do you want to make decisions for you? (3) If you were left significantly impaired after an attempt at resuscitation, under what circumstances would you want us to discontinue life-sustaining care? Additionally, preferences for resuscitation are best understood in the context of an individual’s values, beliefs, relationships, and culture.⁷

Many problematic end-of-life issues can be traced to a focus on interventions (“Would you wish to be intubated?”) without an adequate exploration of values (“What do you value about your life? What are the things that make your life worth living?”). It is also a mistake to think about advance directives as an issue limited to end-of-life situations. Advance directives are really just part of informed consent for any treatment, and discussion of advance directives is an important aspect of good medical care.

Informed Decision Making (Informed Consent)

In the United States, individuals are free to develop their own conceptions of happiness or a good life. By extension, choices about medical tests or treatment are made by patients in ways that maximize the likelihood of that good being achieved. This is called *patient autonomy*, and some would call it one of the core principles that define the relationship between a doctor and a patient. Respecting autonomy requires respect for the values and wishes of the individual. Additionally, the exercise of autonomy requires adequate information, the power of reason, and freedom of choice. Shared decision making happens when an autonomous individual has a conversation with the physician that incorporates the patient’s values (autonomy) and the values of the physician.

Brock discussed the basic requirements for informed consent and identified three critical elements: the person giving consent must be competent, informed, and able to make a decision free from coercion.¹³ *Competence* has several critical elements.¹⁴ First, the decision maker must be capable of understanding relevant information, which involves both memory and mental processing. Second, it requires the ability

to attend to and retain information, the ability to manipulate information, and the ability to foresee consequences. The third element is the ability to formulate and communicate choice. Some standards of competency strengthen this requirement by demanding the ability to communicate a *stable* choice (in this case, ambivalence may be a sign of incompetence).

To adequately participate in medical decision making, patients must have enough information to weigh the risks and benefits of various medical interventions. In the past, the standard for being informed was the standard practice of other physicians in the community.¹⁵ Subsequently, *informed* came to mean what a “reasonable person would want to know.” Because the main point of informed consent is to respect the rights and values of individuals, it is most appropriate to address this issue in terms of what a particular patient needs to know.¹⁶ In general, patients need to know about the illness and its natural history to make informed decisions about medical care. They need information about the effectiveness of treatment, the risks of treatment, and the likelihood of success with treatment. This information must be presented in a way that is understandable to the patient, at an appropriate educational level, and is in the patient’s language. Whether enough information has been transmitted can be assessed at the most basic level by simply asking a patient whether he or she has any questions. Brock writes of “informed understanding” and notes that this “permits an informed exercise in self-determination and promotes a decision most in accord with the patient’s well-being.”¹³ In addition, this approach values autonomy.

The decision must also be voluntary—that is, free of coercion. The decision maker must have the freedom to accept or refuse the intervention or test being proposed. Consent given as a result of undue coercion is generally not valid.

Informed consent in the ICU raises some special issues. First, as mentioned earlier, the decision maker is often a surrogate rather than the patient. The surrogate decision maker should have access to all relevant information the patient would need to make informed decisions; however, the surrogate should not routinely be given confidential information *simply because the patient is no longer competent*. An example may be helpful in illustrating this point. An HIV-positive patient in the ICU has designated a family member as his surrogate; however, the family is unaware of his HIV status. The ICU physician believes a central line is indicated for continued care and seeks informed consent from the family member. In this case, it may be possible to obtain true informed consent for the procedure without divulging the patient’s HIV status. Alternatively, a decision about a test or treatment specifically related to the patient’s HIV status may require that this information be divulged to the surrogate for him or her to make an informed decision.
